CONTENTS

NUMBER 1, JANUARY, 1949

Studies in Diabetic Acidosis and Coma, with Particular Emphasis on the Retention of Administered Potassium. T. S. DANOWSKI, J. H. PETERS, J. C. RATUBEN, J. M. QUASHNOCK, AND L. GRUENMAN.....	1
Simultaneous Measurement of Effective Renal Blood Flow and Cardiac Output in Resting Normal Subjects and Patients with Essential Hypertension. ALFRED A. BOLOMEY, ALEXANDER J. MICHEL, CATHARINE MICHEL, ERNEST S. BREED, GEORGE E. SCHREINER, AND HENRY D. LAUSON.....	10
Use of Blood Donors with Positive Serologic Tests for Syphilis—with a Note on the Disappearance of Passively Transferred Reagin. MARK M. RAVITCH, THOMAS W. FARMER, AND BARBARA DAVIS.....	18
Human Prothrombin: Quantitative Studies on the Plasma Labile Factor and the Restorative Effects of Normal, Hypofibrinogenemic, and Hemophilic Plasma on the Prothrombin of Stored Plasma. BENJAMIN ALEXANDER AND ANDRE DE VRIES.....	24
A Study of the Rate of Disappearance of a Digitalis Glycoside (Lanatoside C.) from the Blood of Man. MEYER FRIEDMAN AND RENÉ BINE, JR.....	32
The Renal Regulation of Acid-Base Balance in Man. III. The Reabsorption and Excretion of Bicarbonate. R. F. PITTS, J. L. AYER, AND W. A. SCHUESS.....	35
The Bioassay of Adrenal Corticoids in the Urine of Patients with Congestive Heart Failure. ALVIN E. PARRISH.....	45
Autoantibodies in Human Glomerulonephritis. KURT LANGE, MICHAEL M. A. GOLD, DAVID WEINER, AND VERA SIMON.....	50
The Hyaluronic Acid of Synovial Fluid in Rheumatoid Arthritis. CHARLES RAGAN AND KARL MEYER.....	56
Blood Oxygen Studies in Patients with Polycythemia and in Normal Subjects. L. R. WASSERMAN, R. L. DOBSON, AND J. H. LAWRENCE.....	60
The Phosphorus Turnover of Carcinoma of the Human Stomach as Measured with Radioactive Phosphorus. JOHN SCHULMAN, JR., MARLENE FALKENHEIM, AND SEYMOUR J. GRAY.....	66
Chemical, Clinical, and Immunological Studies on the Products of Human Plasma Fractionation. XXXVII. The Metal-Combining Globulin of Human Plasma. DOUGLAS M. SURGENOR, BERNARD A. KOECHLIN, AND LAURENCE E. STRONG.....	73
Chemical, Clinical, and Immunological Studies on the Products of Human Plasma Fractionation. XXXVIII. Serum Iron Transport. CHARLES E. RATH AND CLEMENT A. FINCH.....	79
Chemical, Clinical, and Immunological Studies on the Products of Human Plasma Fractionation. XXXIX. The Anemia of Infection. Studies on the Iron-Binding Capacity of Serum. G. E. CARTWRIGHT AND M. M. WINTROBE.....	86
Potassium Deficiency and the Role of the Kidney in its Production. ROBERT TARAIL AND J. RUSSELL ELKINTON.....	99
Can Vascular Shunting Be Induced in the Kidney by Vasoactive Drugs? FRANÇOIS C. REUBI AND HENRY A. SCHROEDER.....	114
Electrophrenic Respiration. II. Its Use in Man. JAMES L. WHITTENBERGER, STANLEY J. SARNOFF, AND ESTHER HARDENBERGH.....	124
The Volume of the Lung Determined by Helium Dilution. Description of the Method and Comparison with Other Procedures. GEORGE R. MENEELY AND NOLAN L. KALTREIDER.....	129
Studies on Human Alcaptonuria. Effect of Thiouracil, Para-Aminobenzoic Acid and Di-Iodotyrosine on Excretion of Homogentisic Acid. ABRAHAM G. WHITE, JULIUS G. PARKER, AND FRANK BLOCK.....	140

The Significance of the Difference in Systemic Arterial and Venous Plasma Concentrations in Renal Clearance Methods. CLAUS BRUN, TAGE HILDEN, AND FLEMMING RAASCHOU....	144
Studies on Pain: Measurements of Pain Intensity in Childbirth. JAMES D. HARDY AND CARL T. JAVERT.....	153
Methods for Measuring the Activity of Components of the Streptococcal Fibrinolytic System, and Streptococcal Desoxyribonuclease. L. R. CHRISTENSEN.....	163
The Effect in Patients of Streptococcal Fibrinolysin (Streptokinase) and Streptococcal Desoxyribonuclease on Fibrinous, Purulent, and Sanguinous Pleural Exudations. WILLIAM S. TILLET AND SOL SHERRY.....	173

NUMBER 2, MARCH, 1949

The Behavior of Radioiodine in the Blood. WILLIAM M. MCCONAHEY, F. RAYMOND KEATING, JR., AND MARSCHELLE H. POWER.....	191
Induced Insulin Resistance in the Rabbit. FRANCIS C. LOWELL AND WILLIAM FRANKLIN...	199
Relative Measurement <i>In Vivo</i> of Accumulation of Radioiodine by the Human Thyroid Gland: Comparison with Radioactivity in Peripheral Tissues. THOMAS J. LUELLEN, F. RAYMOND KEATING, JR., MARVIN M. D. WILLIAMS, JOSEPH BERKSON, MARSCHELLE H. POWER, AND WILLIAM M. MCCONAHEY.....	207
The Measurement of the Iodine-Accumulating Function of the Human Thyroid Gland. F. RAYMOND KEATING, JR., J. C. WANG, THOMAS J. LUELLEN, MARVIN M. D. WILLIAMS, MARSCHELLE H. POWER, AND WILLIAM M. MCCONAHEY.....	217
The Validity of the Electrokymographic Method for Measurement of Diameter Change of the Aorta and Pulmonary Artery during Circulatory Disturbance. CALVIN F. KAY, JAMES W. WOODS, JR., HARRY F. ZINSSER, JR., AND J. MALVERN BENJAMIN, JR.....	228
Studies of the Role of the Liver in Human Carbohydrate Metabolism by the Venous Catheter Technic. I. Normal Subjects under Fasting Conditions and following the Injection of Glucose. PHILIP K. BONDY, DAVID F. JAMES, AND BETTY W. FARRAR.....	238
Metabolic Studies on Protein-Depleted Patients Receiving a Large Part of their Nitrogen Intake from Human Serum Albumin Administered Intravenously. CHRISTINE WATERHOUSE, SAMUEL H. BASSETT, AND JACOB W. HOLLER.....	245
Congenital Methemoglobinemia. A Clinical and Biochemical Study of a Case. HOWARD A. EDER, CLEMENT FINCH, AND RALPH W. MCKEE.....	265
The Effects of Induced Malaria, Acute Starvation and Semi-Starvation on the Electrophoretic Diagram of the Serum Proteins of Normal Young Men. HENRY LONGSTREET TAYLOR, OLAF MICKELSEN, AND ANCEL KEYS.....	273
Complement and its Components in Human Cerebrospinal Fluid. MICHAEL HEIDELBERGER AND ROBERT H. MULLER.....	282
Hematologic Observations in Patients with Chronic Hepatic Insufficiency. THOMAS JARROLD AND RICHARD W. VILTER.....	286
The Cardiovascular Effects of Acutely Induced Hypothermia. O. PREC, R. ROSENMAN, K. BRAUN, S. RODBARD, AND L. N. KATZ.....	293
The Circulatory Responses to Hyperthermia Induced by Radiant Heat. O. PREC, R. ROSENMAN, K. BRAUN, R. HARRIS, S. RODBARD, AND L. N. KATZ.....	301
The Relation of Influenza Virus and Bacteria in the Etiology of Pneumonia. ELIZABETH STARBUCK MAXWELL, THOMAS G. WARD, AND THOMAS E. VAN METRE, JR.....	307
Determination of the Plasma Glycine after Gelatin Feeding as a Diagnostic Procedure for Pancreatic Fibrosis. HALVOR N. CHRISTENSEN AND HARRY SHWACHMAN.....	319
Studies in Cirrhosis of the Liver. I. Relationship between Plasma Volume, Plasma Protein Concentrations and Total Circulating Proteins. GLENN I. HILLER, ELSTON R. HUFFMAN, AND STANLEY LEVEY.....	322

The Agglutination of Autoclaved Hemolytic Streptococci by Serum from Patients with Rheumatic Fever and Other Conditions. SENG J. LIAO.....	331
The Clotting Behavior of Human "Platelet-Free" Plasma: Evidence for the Existence of a "Plasma Thromboplastin." C. LOCKARD CONLEY, ROBERT C. HARTMANN, AND WILLIAM I. MORSE, II.	340
The Hemodynamic Effects of Hypotensive Drugs in Man. I. Veratrum Viride. EDWARD D. FREIS, JOSEPH R. STANTON, JAMES W. CYLBERG, JULIUS LITTE, MEYER H. HALPERIN, CHARLES H. BURNETT, AND ROBERT W. WILKINS.....	353
Some Observations on the Ballistocardiographic Pattern, with Special Reference to the H and K Waves. JOHN L. NICKERSON.....	369
Transfers of Potassium in Renal Insufficiency. J. RUSSELL ELKINTON, ROBERT TARAIL, AND JOHN P. PETERS.....	378
Complement and its Component Fractions in Cerebrospinal Fluid in Inflammatory Cerebrospinal Diseases. SOPHIE SPICER, EMANUEL APPELBAUM, AND DAVID D. RUTSTEIN.....	389
The Effect of Adrenocorticotrophic Hormone in Congenital Adrenal Hyperplasia with Virilism and in Cushing's Syndrome Treated with Methyl Testosterone. ROGER A. LEWIS AND LAWSON WILKINS.....	394
A Brief Sketch of the History of the American Society for Clinical Investigation. J. HAROLD AUSTIN.....	401

NUMBER 3, MAY, 1949

Some Observations on the Development of Hypokalemia during Therapy of Diabetic Acidosis in Juvenile and Young Adult Subjects. L. GREENMAN, F. M. MATEER, R. C. GOW, J. H. PETERS, AND T. S. DANOWSKI.....	409
The Effect of Bilateral Stellate Ganglion Block on the Cerebral Circulation in Normotensive and Hypertensive Patients. M. H. HARMEL, J. H. HAFKENSCHIEL, G. M. AUSTIN, C. W. CRUMPTON, AND S. S. KETY.....	415
Peptidase Activity in Human Serum Following Bone Fracture. KARL STERN, ANDREA M. CULLEN, AND VIRGINIA T. BARBER.....	419
The Renal Regulation of Acid-Base Balance in Man. IV. The Nature of the Renal Compensations in Ammonium Chloride Acidosis. O. W. SARTORIUS, J. C. ROEMMELT, AND R. F. PITTS.....	423
The Effects of Histamine on Renal Function in Hypertensive and Normotensive Subjects. F. C. REUBI AND P. H. FUTCHER.....	440
Studies of Coproporphyrin. I. The Per Diem Excretion and Isomer Distribution of Coproporphyrin in Normal Human Urine. CECIL JAMES WATSON, VIOLET HAWKINSON, SAMUEL SCHWARTZ, AND DONALD SUTHERLAND.....	447
Studies of Coproporphyrin. II. An Investigation of the Contribution to the Urinary Coproporphyrin of Hemoglobin and of Bacterial Metabolism in the Intestinal Tract. EVREL A. LARSON AND CECIL JAMES WATSON.....	452
Studies of Coproporphyrin. III. Idiopathic Coproporphyrinuria; a Hitherto Unrecognized Form Characterized by Lack of Symptoms in Spite of the Excretion of Large Amounts of Coproporphyrin. CECIL JAMES WATSON, SAMUEL SCHWARTZ, WILLIAM SCHULZE, LEON O. JACOBSON, AND RALPH ZAGARIA.....	465
Intra-Articular Temperature as a Measure of Joint Reaction. STEVEN M. HORVATH AND JOSEPH L. HOLLANDER.....	469
III. The Fate of Citrate in Erythroblastotic Infants Treated with Exchange Transfusion. IRVING B. WEXLER, JOSEPH B. PINCUS, SAMUEL NATELSON, AND JULIUS K. LUGOVOY... ..	474
Electrolyte Changes in Human Striated Muscle in Acidosis and Alkalosis. GILBERT H. MUDGE AND KATHERINE VISLOCKY.....	482

Studies on Free Erythrocyte Protoporphyrin, Serum Iron, Serum Iron-Binding Capacity and Plasma Copper During Normal Pregnancy. JANE FAY, G. E. CARTWRIGHT, AND M. M. WINTROBE.....	487
Studies on the Activation of a Serum "Prothrombin-Converting Factor." RALPH F. JACOX	492
Studies in Iron Transportation and Metabolism. VII. Evidence Obtained with Radioactive Iron that "Easily Split-Off" Blood Iron is an Artefact. MOISES GRINSTEIN AND CARL V. MOORE.....	505
A Comparison of the Direct Fick and the Grollman Methods for Determination of the Cardiac Output in Man. LARS WERKÖ, STIG BERSEUS, AND HENRIK LAGERLÖF.....	516
A Factor Determining the Location of Pseudofractures in Osteomalacia. M. LE MAY AND J. W. BLUNT, JR.....	521
The Oxygen Consumption of the Normal and the Diseased Human Kidney. WALTER H. CARGILL AND JOHN B. HICKAM.....	526
The Measurement of Glomerular and Tubular Plasma Flow in the Normal and Diseased Human Kidney. WALTER H. CARGILL.....	533
Hypervolemic Anemia in Cirrhosis. JEANNE C. BATEMAN, HAROLD M. SHORR, AND TORBJORN ELGVIN.....	539
The Effect of Hyaluronidase on the Absorption of Parenterally Administered Radioactive Plasma Proteins in the Dog. HENRY H. BANKS, ARNOLD M. SELIGMAN, AND JACOB FINE	548
The Acceleration of Linear Flow in the Deep Veins of the Lower Extremity of Man by Local Compression. JOSEPH R. STANTON, EDWARD D. FREIS, AND ROBERT W. WILKINS.....	553
The Effect of Exercise and Body Position on the Venous Pressure at the Ankle in Patients Having Venous Valvular Defects. ALBERT A. POLLACK, BOWEN E. TAYLOR, THOMAS T. MYERS, AND EARL H. WOOD.....	559
The Inhibition of Frostbite Wheals by the Iontophoresis of Antihistaminic Agents. MARTIN B. MACHT, MORTIMER E. BADER, AND JERE MEAD.....	564
The Construction of Normal Standards for Cardiac Output in Man. J. M. TANNER.....	567

NUMBER 4, JULY, 1949

An Evaluation of Human Serum Albumin in the Treatment of Cirrhosis of the Liver. WILLIAM W. FALON, RICHARD D. ECKHARDT, T. LYNCH MURPHY, ARNOLD M. COOPER, AND CHARLES S. DAVIDSON.....	583
The Effect of Human Serum Albumin, Mercurial Diuretics, and a Low Sodium Diet on Sodium Excretion in Patients with Cirrhosis of the Liver. WILLIAM W. FALON, RICHARD D. ECKHARDT, ARNOLD M. COOPER, AND CHARLES S. DAVIDSON.....	595
Improvement of Active Liver Cirrhosis in Patients Maintained with Amino Acids Intravenously as the Source of Protein and Lipotropic Substances. RICHARD D. ECKHARDT, WILLIAM W. FALON, AND CHARLES S. DAVIDSON.....	603
The Effects of Dihydroergocornine on the Circulation in the Extremities of Man. DANIEL W. HAYES, KHALIL G. WAKIM, BAYARD T. HORTON, AND GUSTAVUS A. PETERS.....	615
Studies of Coproporphyrin. IV. The Per Diem Excretion and Isomer Distribution in the Urine in Infectious Hepatitis, Infectious Mononucleosis, and Mechanical Jaundice. CECIL JAMES WATSON, VIOLET HAWKINSON, RICHARD B. CAPPS, AND EMANUEL M. RAPPAPORT	621
Studies on Vasomotor Tone. I. The Effect of the Tetraethylammonium Ion on the Peripheral Blood Flow of Normal Subjects. SIBLEY W. HOOBLER, S. DONALD MALTON, H. THOMAS BALLANTINE, JR., SAUL COHEN, ROSALIE B. NELIGH, M. M. PEET, AND RICHARD H. LYONS.....	638
The Effect of Anoxic Anoxia on the Human Kidney. EUGENE Y. BERGER, MORTON GALDSTON, AND SEYMOUR A. HORWITZ.....	648

Determination of Adrenergic and Cholinergic Substances in the Blood of Man. MARC J. MUSSER AND ELIZABETH A. GRIMM.....	653
Concentration-Time Course in the Plasma of Man of Radiomercury Introduced as a Mercurial Diuretic. S. A. THREEFOOT, C. T. RAY, G. E. BERCH, J. A. CROSVICH, J. P. MILNOR, W. OVERMAN, AND W. GORDON.....	661
A Study of Certain Aspects of Blood Coagulation in the Postoperative State in Congestive Heart Failure and in Thrombophlebitis. NOMIE O. FOWLER.....	671
Studies of Lung Volumes and Intrapulmonary Mixing: Notes on Open-Circuit Methods, Including Use of a New Pivoted Type Gasometer for Lung Clearance Studies. J. B. BATEMAN, WALTER M. BOOTHBY, AND H. FREDERIC HELMHOLTZ, JR.....	679
Observations on the Proteolytic Activity <i>In Vitro</i> at Neutral Reaction of Gastric Juice from Patients with Sprue. HERBERT J. FOX.....	687
Sodium and Chloride Depletion in Acute Porphyria with Reference to the Status of Adrenal Cortical Function. F. T. G. PRUNTY.....	690
Treatment of Nephrosis with Concentrated Human Serum Albumin. I. Effects on the Proteins of Body Fluids. JOHN A. LUETSCHER, JR., ALASTAIR D. HALL, AND VIRGINIA L. KREMER.....	700
Mucolytic Enzyme Systems. VIII. Inhibition of Hyaluronidase by Human Blood Serum During the Normal Menstrual Cycle and Pregnancy. ERICK Y. HAKANSON AND DAVID GLICK.....	713
Studies on Amino Acid Excretion in Man. III. Amino Acid Levels in Plasma and Urine of Normal Men Fed Diets of Varying Protein Content. JOSEPH B. KIRSNER, A. LEONARD SHEFFNER, AND WALTER LINCOLN PALMER.....	716
Factors in the Treatment of Laennec's Cirrhosis. I. Clinical and Histological Changes Observed During a Control Period of Bed-Rest, Alcohol Withdrawal, and a Minimal Basic Diet. GERALD KLATSKIN AND RAYMOND YESNER.....	723
Oxygen Saturation of Sternal Marrow Blood in Polycythemia Vera. BERNARD M. SCHWARTZ AND DANIEL STATS.....	736
IV. Response of Citric Acid Levels of Normal Adults and Children to Intramuscular Injection of Epinephrine. JOSEPH B. PINCUS, SAMUEL NATELSON, AND JULIUS K. LUGOVY.....	741
Studies of the Effects of Flavonoids on Roentgen Irradiation Disease. II. Comparison of the Protective Influence of Some Flavonoids and Vitamin C in Dogs. JOHN B. FIELD AND PAUL E. REKERS.....	746
The Plasma Viscosity in Pulmonary Tuberculosis and Rheumatic Diseases. JOHN HOUSTON, R. B. WHITTINGTON, I. C. COWAN, AND JOHN HARKNESS.....	752
Proceedings of the Forty-first Annual Meeting of the American Society for Clinical Investigation, Held in Atlantic City, N. J., May 2, 1949.....	764

NUMBER 5, PART 1, SEPTEMBER, 1949

SYMPOSIUM ON ANTIBIOTICS

Foreword.....	i
The Elimination of Penicillin G in Bilaterally Nephrectomized Dogs. WILLIAM H. ANDERSON AND ROLF BRODERSEN.....	821
Studies on Hypersensitivity to Penicillin. I. Incidence of Reactions in 1303 Patients. MARK H. LEPPER, HARRY F. DOWLING, JAY A. ROBINSON, THOMAS E. STONE, ROBERT L. BRICKHOUSE, ESTON R. CALDWELL, JR., AND RICHARD L. WHELTON.....	826
The Recovery of Bacteria from the Toxic Effects of Penicillin. HARRY EAGLE.....	832
Amperometric Micro-Titration of Streptomycin and Dihydrostreptomycin. JOHN B. CONN AND SARA L. NORMAN.....	837

9

A New Linear Diffusion Method for the Microbiological Assay of Streptomycin and Dihydrostreptomycin. J. M. McGUIRE, W. W. DAVIS, T. V. PARKE, AND W. A. DAILY.....	840
Quantitative Determination of Dihydrostreptomycin by Periodate Oxidation. EDWARD A. GARLOCK, JR., AND DONALD C. GROVE.....	843
Investigations on the Streptomycins. GEOFFREY RAKE, FELIX PANSY, WILLIAM P. JAMBOR, AND RICHARD DONOVICK.....	846
The Effect of Streptomycin Derivatives on Streptomycin-Dependent and -Resistant Strains of Bacteria. WALTER A. WINSTEN.....	850
The Development of Resistance of <i>Salmonella Typhosa</i> to the Fatty Acid Salts of Streptomycin and Dihydrostreptomycin. HENRY WELCH, HENRY FISCHBACH, C. W. PRICE, AND C. H. SHAFFER.....	856
The Effects of Normal Horse Serum on the <i>In Vitro</i> Activity of Tyrothricin. ROBERT J. REEDY AND STANLEY W. WOLFSON.....	861
<i>In Vitro</i> Studies on Possible Synergistic Action Between Penicillin and Bacitracin. MARVIN C. BACHMAN.....	864
Comparison of the Action of Streptomycin, Polymyxin B., Aureomycin and Chloromycetin on <i>H. Pertussis</i> , <i>H. Parapertussis</i> , <i>H. Influenzae</i> and Five Enteric Strains of Gram-Negative Bacilli. HATTIE E. ALEXANDER, GRACE LEIDY, AND WINIFRED REDMAN.....	867
Experimental Studies on the Action of Streptomycin, Aureomycin, and Chloromycetin on <i>Brucella</i> . ELLARD M. YOW AND WESLEY W. SPINK.....	871
Antigenic and Enzyme System Changes in Beta Hemolytic Streptococci Resistant to Penicillin, Streptomycin, Bacitracin and Aureomycin. HORACE M. GEZON AND DORCAS M. FASAN.....	886
Patterns of Bacterial Resistance to Penicillin, Aureomycin, and Streptomycin. M. DEMEREC.....	891
The Partial Purification and Properties of Antibiotic Substances from the Sweet Potato Plant (<i>Ipomoea Batatas</i>). B. H. BRUCKNER, HAZEL H. MCKAY, P. S. SCHAFFER, AND THOMAS D. FONTAINE.....	894
The Partial Purification and Properties of Antibiotic Substances from the Banana (<i>Musa Sapientum</i>). WILLIAM E. SCOTT, HAZEL H. MCKAY, P. S. SCHAFFER, AND THOMAS D. FONTAINE.....	899
Antibiotic Studies on an Extract from <i>Leptotaenia Multifida</i> . G. A. MATSON, A. RAVVE, J. M. SUGIHARA, AND W. J. BURKE.....	903
Factors Influencing the Antibiotic Activity of Lupulon. YIN-CH'ANG CHIN, NAI-CH'U CHANG, AND HAMILTON H. ANDERSON.....	909
Lupulon and Humulon—Antibiotic Constituents of Hops. J. C. LEWIS, GORDON ALDERTON, J. F. CARSON, D. M. REYNOLDS, AND W. D. MACLAY.....	916
The Occurrence of Antibacterial Substances Active Against <i>Mycobacterium Tuberculosis</i> in Seed Plants. R. Y. GOTTSALL, E. H. LUCAS, ARDETH LICKFELDT, AND J. M. ROBERTS.....	920
A Crystalline Antifungal Agent, Mycosubtilin, Isolated from Subtilin Broth. ROBERT B. WALTON AND H. BOYD WOODRUFF.....	924
The Antifungal Activity of Antibiotic XG. GLADYS L. HOBBY, PETER P. REGNA, NANCY DOUGHERTY, AND WILLIAM E. STIEG.....	927
Neomycin—Production and Antibiotic Properties. SELMAN A. WAKSMAN, HUBERT A. LECHEVALIER, AND DALE A. HARRIS.....	934
Diffusion Plate Assay for Chloramphenicol and Aureomycin. W. A. RANDALL, A. KIRSHBAUM, J. K. NIELSEN, AND D. WINTERMERE.....	940
Chloramphenicol (Chloromycetin), an Antibiotic. Pharmacological and Pathological Studies in Animals. O. M. GRUHZIT, R. A. FISKEN, T. F. REUTNER, AND EDITH MARTINO.....	943
Susceptibility of Micro-Organisms to Chloramphenicol (Chloromycetin). I. W. MCLEAN, JR., J. L. SCHWAB, A. B. HILLEGAS, AND A. S. SCHLINGMAN.....	953
Preliminary Report on the Use of Chloramphenicol (Chloromycetin) in the Treatment of Acute Gonorrheal Urethritis. J. E. SMADEL, C. A. BAILEY, AND D. S. MANKIKAR.....	964

The Beneficial Effect of Chloromycetin in Brucellosis. THEODORE E. WOODWARD, JOSEPH E. SMADEL, WILLIAM A. HOLBROOK, AND WILLIAM T. RAHY.....	968
The Effect of Aureomycin Against <i>Bacterium Tularensis</i> . JOHN C. RANSMER.....	977
The Concentration of Aureomycin in Urine and Cerebrospinal, Pleural and Ascitic Fluids after Oral and Intravenous Administration. HARRY F. DOWLING, MARK H. LEPPER, ESTON R. CALDWELL, JR., RICHARD L. WHELTON, AND ROBERT L. BRICKHOUSE.....	983
Clinical Experience with Aureomycin. JOHN C. HARVEY, GEORGE S. MIRICK, AND ISABELLE G. SCHAUB.....	987
The Clinical Evaluation of Aureomycin. HENRY BRAINERD, EDWIN H. LENNETTE, GORDON MEIKLEJOHN, HENRY B. BRUYN, JR., AND WILLIAM H. CLARK.....	992
Further Experiences with Intravenous Aureomycin Therapy. A Study of 116 Cases. MURRAY SANDERS, JOHN M. REMMALL, CYRIL SOLOMON, M. GONZALEZ SORET, AND NELDA I. RICCI.....	1006
Purity Studies on Polypeptide Antibiotics: Bacitracin. LYMAN C. CRAIG, J. DELAFIELD GREGORY, AND GEY T. BARRY.....	1014
A Comparative Study of the Renal Damage Produced in Mice by Various Lots of Bacitracin. LAWRENCE W. SMITH, FRED H. SCHULTZ, JR., WALLACE L. OTT, AND HARTZELL G. PAYNE.....	1018
Chemical Studies on Polymyxin B. PETER P. REGNA, I. A. SOLOMONS, BERNARD K. FORSCHER, AND ALBERT E. TIMRECK.....	1022
Laboratory and Clinical Studies of Polymyxin B and E. EDWIN J. PULASKI, HINTON J. BAKER, MILTON L. ROSENBERG, AND JAMES F. CONNELL, JR.....	1028
The Pharmacology of Circulin. MILTON J. VANDER BROOK AND MARILYN T. RICHMOND....	1032
Preparation of a Modified Subtilin Suitable for the Treatment of Tuberculosis and Other Infections in Animals. A. J. SALLE AND GREGORY J. JANN.....	1036
Abstracts.....	1039

NUMBER 5, PART 2, SEPTEMBER, 1949

The Serum Proteins in Infectious Mononucleosis. Electrophoretic Studies. KENNETH STERLING.....	1057
Evidence that Renal Sodium Excretion by Normal Human Subjects is Regulated by Adrenal Cortical Activity. ALEXANDER LEAF AND WILLIAM T. COUTER.....	1067
Some Effects of Variation in Sodium Intake and of Different Sodium Salts in Normal Subjects. ALEXANDER LEAF, WILLIAM T. COUTER, AND L. H. NEWBURGH.....	1082
Further Studies with the Salt Tolerance Test in Normal Individuals and in Patients with Adrenal Cortical Hyperfunction. L. J. SOFFER, J. L. GABRILOVE, AND M. D. JACOBS....	1091
The Action of Streptococcal Desoxyribose Nuclease (Streptodornase), <i>In Vitro</i> and on Purulent Pleural Exudates of Patients. SOL SHERRY, ALAN JOHNSON, AND WILLIAM S. TILLET.....	1094
Studies with Radioactive Iodized Fat. I. Preparation of Radioactive Fat with Observations on the Absorption of Fat following Subcutaneous and Intraperitoneal Injection in Dogs. ALEXANDER M. RUTENBURG, ARNOLD M. SELIGMAN, AND JACOB FINE.....	1105
Studies with Radioactive Iodized Fat. II. The Tissue Distribution of Emulsified Fat following Intravenous Administration. ALEXANDER M. RUTENBURG, ARNOLD M. SELIGMAN, AND JACOB FINE.....	1110
The Measurement of Extracellular Fluid in Man by Means of a Constant Infusion Technique. IRVING L. SCHWARTZ, DAVID SCHACHTER, AND NORBERT FREINKEL.....	1117
Studies of the Role of the Liver in Human Carbohydrate Metabolism by the Venous Catheter Technic. II. Patients with Diabetic Ketosis, Before and After the Administration of Insulin. PHILIP K. BONDY, WALTER LYON BLOOM, VIRGINIA S. WHITNER, AND BETTY W. FARRAR.....	1126

Studies of the Pulmonary Circulation. I. The Circulation Time from the Pulmonary Artery to the Femoral Artery and the Quantity of Blood in the Lungs in Normal Individuals. RICHARD V. EBERT, CRAIG W. BORDEN, HERBERT S. WELLS, AND RUSSELL H. WILSON. . .	1134
Studies of the Pulmonary Circulation. II. The Circulation Time from the Pulmonary Artery to the Femoral Artery and the Quantity of Blood in the Lungs in Patients with Mitral Stenosis and in Patients with Left Ventricular Failure. CRAIG W. BORDEN, RICHARD V. EBERT, RUSSELL H. WILSON, AND HERBERT S. WELLS.	1138
Maturation of Renal Function in Childhood: Clearance Studies. MITCHELL I. RUBIN, ERIKA BRUCK, AND MILTON RAPOPORT.	1144
The Cerebral Blood Flow in Male Subjects as Measured by the Nitrous Oxide Technique. Normal Values for Blood Flow, Oxygen Utilization, Glucose Utilization, and Peripheral Resistance, with Observations on the Effect of Tilting and Anxiety. PERITZ SCHEINBERG AND EUGENE A. STEAD, JR.	1163
Serological Studies in Rheumatic Fever. II. Serum Complement in the Rheumatic State. EDWARD E. FISCHER, RUTH H. PAULI, AND JACK LESH.	1172
Evaluation of Therapeutic Substances Employed for the Relief of Bronchospasm. V. Adrenergic Agents. ELLIOTT BRESNICK, JOHN F. BEAKEY, LEON LEVINSON, AND MAURICE S. SEGAL.	1182
Evaluation of Therapeutic Substances Employed for the Relief of Bronchospasm. VI. Aminophylline. MAURICE S. SEGAL, LEON LEVINSON, ELLIOTT BRESNICK, AND JOHN F. BEAKEY.	1190
Chloramphenicol (Chloromycetin) in the Treatment of Tsutsugamushi Disease (Scrub Typhus). JOSEPH E. SMADEL, THEODORE E. WOODWARD, HERBERT L. LEY, JR., AND RAYMOND LEWTHWAITE.	1196
Changes in Liver Glycogen Studied by the Needle Aspiration Technic in Patients with Diabetic Ketosis. With a Method for the Estimation of Glycogen from Histologic Preparations. PHILIP K. BONDY, WALTER H. SHELDON, AND LILLIAN D. EVANS.	1216
Comparisons of the Distribution of Radioactive Iodine in Serum and Urine in Different Levels of Thyroid Function. ROBERT H. WILLIAMS, HERBERT JAFFE, AND BEATRICE BERNSTEIN	1222
Effects of Adrenocorticotrophic Hormone on Neuro-Muscular Function in Patients with Myasthenia Gravis. CLARA TORDA AND HAROLD G. WOLFF.	1228
The Serum Proteins in Portal Cirrhosis under Medical Management. Electrophoretic Studies. KENNETH STERLING, WILLIAM E. RICKETTS, JOSEPH B. KIRSNER, AND WALTER L. PALMER.	1236

NUMBER 6, PART 1, NOVEMBER, 1949

SYMPOSIUM ON RADIOACTIVE ISOTOPES

Foreword.	i
Production and Availability of Radioisotopes. PAUL C. AEBERSOLD.	1247
The Use of Stable Isotopes in Biological and Medical Research. IRVING M. LONDON.	1255
Dosage Determination in the Use of Radioactive Isotopes. LEONIDAS D. MARINELLI.	1271
Personnel Protection in the Use of Radioactive Isotopes. G. FAILLA.	1281
Biological Hazards and Toxicity of Radioactive Isotopes. AUSTIN M. BRUES.	1286
Equations for Tracer Experiments. A. K. SOLOMON.	1297
The Therapeutic Application of Radioactive Phosphorus with Special Reference to the Treatment of Primary Polycythemia and Chronic Myeloid Leukemia. HYMER L. FRIEDEL AND JOHN P. STORAASLI.	1308
Radioactive Phosphorus in Studies on the Metabolism of Normal and Neoplastic Tissues. A. MARSHAK.	1324

The Use of Radioactive Iodine in Studying the Pathologic Physiology of Thyroid Disease. RULON W. RAWSON	1330
The Use of Radioiodine in Physiological and Clinical Studies on the Thyroid Gland. M. S. RABEN AND E. B. ASTWOOD	1347
Radioiodine Therapy in Graves' Disease: A Review. MAYO H. SOLEY AND NADINE FOREMAN	1367
The Uptake and Elimination of Krypton and Other Inert Gases by the Human Body. C. A. THOMAS, H. B. JONES, J. H. LAWRENCE, AND J. G. HAMILTON	1375

NUMBER 6, PART 2, NOVEMBER, 1949

The Hemodynamic Effects of Hypotensive Drugs in Man. II. Dihydroergocornine. EDWARD D. FREIS, JOSEPH R. STANTON, JULIUS LITTEr, JAMES W. CULBERTSON, MEYER H. HALPERIN, F. CORBIN MOISTER, AND ROBERT W. WILKINS	1387
The Effect of a Cation Exchange Resin on Electrolyte Balance and its Use in Edematous States. LESLIE IRWIN, EUGENE Y. BERGER, BENJAMIN ROSENBERG, AND ROSLYN JACKENTHAL	1403
Carbon Tetrachloride Poisoning in Man. I. The Mechanisms of Renal Failure and Recovery. JONAS H. SIROTA	1412

trations of sodium and chloride, the chief electrolytes of extracellular fluid and serum, were not increased above the usual range of isotonicity (Table II, at zero point of Period I). As a matter of fact, the concentrations of sodium were abnormally low in five patients. In all of these and in one other the concentrations of chloride in serum, taking 97 m.eq. per liter as the lower limit of normal, were also decreased (24). In view of the dehydration described above, it is immediately apparent that these patients had lost, in keeping with the findings in other series, considerable amounts of the chief extracellular electrolytes, con-

comitant with the losses of electrolytes. It is known, of course, that the losses of electrolytes and abnormally low levels alone been lost, potassium frequently coexist (1), would have been lost, however, an invariable

During the first analysis can occur with normal 0.9 per cent saline of potassium (35) and our concentrations of sodium pronounced hypopotassemia patients (Table II, evident paralysis. It is a fact in all but one can be drawn as to definite hypernatremia and hyponatremia deficits of potassium. In subject R. J., for example, shown, for with normal concentrations, the serum potassium increased to 161.6 m.eq. per liter and hydrocortisone

arbonate: The markedly lowered concentration of serum bicarbonate present on admission toward or to normal during therapy in

all patients. The development of hyperchloremia, which was as has already been noted an almost invariable occurrence, did not prevent these increases in bicarbonate. However, it is not possible to answer unequivocally from these data the question as to whether or not hyperchloremia repressed the rise of serum bicarbonate. It is clear, for example, that the increase during the first period in serum bicarbonate level of 10.9 m.eq. per liter in 20 hours in patient J. K. who did not develop hyperchloremia is quite comparable to the 10.2 m.eq. per liter increase in 19 hours in the patient with the most pronounced hyperchloremia (R. J.). On the other hand, the possibility that hyperchloremia prolonged the acidosis in patient T. W. can by no means be excluded. At 70 hours the bicarbonate concentration was still only

* Balance data are expressed per individual period rather than cumulatively.

† Corrected for the electrolytes and nitrogen withdrawn in serum samples. Stools, when passed, were formed and not analyzed. Small amounts of vomitus in T.W. and 240 cc. in L.D. in the pre-KCl periods were not analyzed.

‡ The K balances represent changes in excess of the transfers associated with the anabolism and catabolism of proteins. Similar treatment of the Na data does not significantly affect the results. Changes in the NPN have been taken into account in calculating the balance of cell nitrogen (17-19).

16.4 m.eq. per liter, even though hyperglycemia and acetonuria had disappeared.

3. *Potassium*: Abnormally high levels of potassium (6.5 and 6.7 m.eq. per liter) were noted on admission twice in the same patient, D. C. (a) and D. C. (b) in Table II. In the other six cases the admission values ranged from 3.4 to 5.5. During the initial period of therapy in which no potassium was given a dramatic fall of serum potassium to abnormally low levels was observed in patients T. W., L. D., R. J., D. C. (a) and D. C. (b). Though the intermediate points are not recorded the values given are actually the lowest concentrations observed in each patient before the start of KCl *per os* or parenterally. Only one of the subjects, R. J., developed obvious muscular paralysis, with inability to move his extremities. As a group, however, the patients were still too ill at the time of most marked hypopotassemia to permit clear differentiation between generalized asthenia and partial paralysis.

The administration of KCl without exception increased the concentration of serum potassium. The highest recorded level, 5.7 m.eq. per liter, at the end of KCl therapy was observed in the one patient, D. C. (b), who received the salt intravenously. However, a comparable or even greater increment from 2.8 to 5.6 m.eq. per liter occurred in patient T. W. who took the KCl *per os*. It is to be noted that the muscular paralysis of subject R. J. cleared promptly following the oral administration of the potassium salt. None of the subjects in this series developed gastrointestinal distress or diarrhea, even though the KCl was administered in capsules or intravenously as rapidly as 1 gm. per hour.

C. Balances of carbohydrate, nitrogen, and electrolytes

Results of calculations based on the data in Tables I and II have been recorded in Table III. During Period I the external balances indicated that, with but one exception, the patients had utilized or stored about one-half and in one instance as much as 96 per cent of the administered carbohydrate. Since the concentration of blood sugar fell in each patient during this interval, it is obvious that the balance was even more positive. Similarly, in the subsequent two periods of

observation, valuated. It is known, of course, predominatelysis and abnormally low levels

However, not may the negative balances was of sufficient magnitudis to cancel entirely the earlier retention of sodic- or chloride. The largest positive balances of dium and of chloride, more than 1500 eq. as to each ion for the three periods, were ried as to T.W., even though this patient was itiated with normal concentrations of sodium a, The ride. This finding is to be contrasted with de- relatively small positive balances of these io by patient L. D. despite initial hypochloremia, by hyponatremia. It should be emphasized, h, be ever, that irrespective of the initial concentrati, is of sodium and chloride in the serum all patient retained these two electrolytes in greater or less p- proportion. Again, as in the interpretation, the positive balances of extracellular water, B, can be taken as evidence of replacement of deficits but it is possible that some of it represents over- treatment. The retained sodium was disparately distributed between the extracellular and cellular fluid. Most of it, and frequently all, remained in the extracellular phase (Table III).

In contrast to the positive balances of sodium, all but one patient lost considerable quantities of body potassium during the first period of treatment. This one patient, T. W., had received, however, a moderate amount of potassium during this interval. During the second period of th-

Furthermore, the per retention of potassium given parenterally bject was of the same order of magnitude served on the average in the six other treated *per os*. As might be predicted, r portion of the retained potassium en- e cellular phase (Table III). The cell es of potassium during the second period, rted for the intracellular balances of nitro- n, ranged from + 98 to + 406 m.eq. In some the experiments sodium left the cells as potas- ptered, but this was by no means an in- e finding. The failure to observe recipro- changes of these two ions more often may been related in part to the lag in the extru- of sodium reported by Conway and Hingerty owing replacement of experimentally induced potassium deficits (27). Given with these large positive balances of po- tassium it is not certain that the deficits had been mpletely corrected in all patients. As a matter fact, in the third period, during which the atake was limited to milk and water, only one of he eight patients developed negative balances of cell potassium in excess of nitrogen. The others were still retaining a part or all of the potassium available to them in the milk ration.

DISCUSSION

The electrolyte, nitrogen, and carbohydrate studies in these patients again emphasize that considerable amounts of body constituents are lost during diabetic coma. The losses of body water, of extracellular electrolytes, of cell nitrogen, and of carbohydrate have been recognized and de- scribed (25, 26). The striking retention of potas-

sium administered to this series of patients points to the existence of concomitant deficits of this cation in the body cells. Such an interpretation is supported by the experiments of Tarail and Elkinton which showed that amounts of potassium as great as those employed in some of our studies were not retained in the body when given by mouth to healthy adults (28). Presumably such subjects do not have potassium deficits and hence the administered potassium is promptly excreted. Diabetic patients in acidosis or coma are, however, depleted of potassium. Several mechanisms appear to be involved in the development of this negative balance. It is obvious, for example, that patients in diabetic acidosis or coma are in negative nitrogen balance. This breakdown of tissue releases potassium bound to protein of cells (17). Similarly, potassium laid down with glycogen in the liver (29) is released from the cells during deglycogenation. These two processes, however, can account for only a small portion of the potassium deficit. Most of the deficit must represent, therefore, a decrease in the cell potassium present in excess of the nitrogen there. Several factors probably contribute to this loss of cell base. First, it is known that extracellular dehydration, *per se*, is associated with movements of potassium and of water out of the cells (17). Secondly, it has been shown that interruption of carbohydrate metabolism in the blood cell *in vitro*, either by refrigeration, exhaustion of glucose stores, or by addition of an inhibitor such as fluoride, is associated with a pouring out of cell potassium (30). Finally, the evidence to date suggests that as long as urine is being elaborated it contains potassium. This appears to be true even though deficits of cell potassium, and even extracellular hypopotassemia, are present (21, 28). Hence, with the diuresis characteristic of almost all patients in coma considerable amounts of potassium are lost. At present it is not clear to which of these mechanisms the major portion of the potassium deficit is to be ascribed.

The hypopotassemia of extracellular fluid which develops during treatment on a potassium-free regimen noted by other workers and by us stems from a number of sources. It is obvious from our data that it results in part from an expansion of body water with the administration of fluids,

and in part from a continued loss of potassium in urine. The negative balances of cell potassium recorded during the first period of therapy in seven of the eight patients exclude the possibility that reentry of this ion into cells played any significant role in the decrease in serum potassium. This does not mean, of course, that no potassium was deposited in the liver with reglycogenation, nor that none entered other cells. It merely indicates that these must have been subsidiary processes. Furthermore, the negative balances of potassium cannot be explained away as manifestations of transfers of chloride into cells. Such a movement of the reference ion could not cancel the negative cell balances, since even large alterations of the chloride space could account for only a few milliequivalents of potassium.

During the administration of potassium salts the major portion of the cation entered the cells. Only a small amount of it was laid down with nitrogen. There was no significant urinary loss of previously retained potassium in the post-KCl periods. As a matter of fact, in five of the experiments more potassium entered the cells. On the whole a smaller proportion of the administered potassium was retained during Period III suggesting that in the majority of the patients cell concentrations of this ion were completely or almost completely restored. It should be emphasized of course that the possibility that the potassium administered orally was incompletely absorbed cannot be excluded. Naturally this would alter the magnitude of the exchanges. However, the findings in control studies (28), and the absence of frequent or diarrheal stools in these patients, suggest that absorption was essentially complete. This is further supported by the finding that quite comparable data were obtained when KCl was given intravenously.

It is to be noted that positive cell balances of both potassium and sodium were recorded in patients who were admitted with essentially normal serum levels of these ions. These instances should again serve to emphasize the fact that the presence of normal concentrations of any particular electrolyte cannot be interpreted as evidence that the total amount is intact (31). This is of obvious importance in planning replacement therapy.

The physiological significance of these extensive potassium deficits can be as yet partially and

only indirectly evaluated. It is known, of course, that muscular paralysis and abnormally low levels of *extracellular* potassium frequently coexist (1, 2, 32-34). This is not, however, an invariable association, since paralysis can occur with normal serum concentrations of potassium (35) and our own data indicate that pronounced hypokalaemia can occur without evident paralysis.

At present only analogies can be drawn as to possible deleterious effects of these deficits of *intracellular* potassium. It has been shown, for example, that the depletion of cellular potassium produced by over-dosage with desoxycortosterone acetate or by restriction of potassium intake is associated with degenerative changes in the myocardium (36, 37). In this respect it is of interest that in our series patient T. W., 26 years of age and previously well, had on admission a grossly abnormal electrocardiogram, characterized by markedly inverted T waves. These changes compatible with myocardial damage were still present one month later, and cleared only after an additional month of convalescence. It may have been more than chance, therefore, that this occurred in the patient who apparently had developed the greatest deficits prior to therapy.

No adequate statistics are yet available as to whether replacement of potassium deficits may mitigate the considerable mortality still associated with diabetic acidosis and coma (26, 38). The favorable results of Govan and Darrow in decreasing the fatality rate of infantile diarrhea by means of parenteral and oral potassium therapy suggest that a similar beneficial response may be expected in diabetic coma (39). In testing this form of therapy, however, unremitting care must be taken to avoid deaths from potassium poisoning (40, 41). At present it would seem reasonable, therefore, to limit the administration of potassium salts to the oral route, or to give only dilute solutions intravenously. An adequate urine volume and constant electrocardiographic surveillance are essential.

SUMMARY AND CONCLUSIONS

Patients recovering from diabetic acidosis or coma retained considerable amounts of potassium administered as KCl, in addition to water, sodium, chloride, carbohydrate, and nitrogen. Comparable positive balances of this cation were re-

corded in one subject during two separate admissions, in one of which KCl was given by mouth and in the other intravenously. In every study potassium entered cells far in excess of amounts which could be ascribed to changes in cell protein. The possible physiological significance of these findings has been discussed.

ACKNOWLEDGMENT

The authors wish to acknowledge their indebtedness to Miss J. Kruman, R.N. and Miss D. Hoehl, R.N. and their assistants, to Miss M. Freedman and her staff of technicians, and to the internes and residents of the two hospitals. Without their help this study would not have been possible.

SIMULTANEOUS MEASUREMENT OF EFFECTIVE RENAL BLOOD FLOW AND CARDIAC OUTPUT IN RESTING NORMAL SUBJECTS AND PATIENTS WITH ESSENTIAL HYPERTENSION¹

By ALFRED A. BOLOMEY,² ALEXANDER J. MICHIE,³ CATHARINE MICHIE,⁴
ERNEST S. BREED, GEORGE E. SCHREINER, AND HENRY D. LAUSON⁵

(From the Departments of Physiology and Medicine, New York University College of Medicine,
and the Third Medical Division [New York University] of Bellevue Hospital,
New York City)

(Received for publication May 14, 1948)

Unpublished data of Bradley and associates (1) indicate that about 25 to 30 per cent of the cardiac output, as measured by the ballistocardiograph (2), perfuses the kidney of healthy adults at rest. This figure has been reported in a review on renal physiology (3). Levy and Blalock (4) obtained an average value of 18.5 per cent in unanesthetized dogs, using the catheterization technique or heart puncture and the direct Fick principle for the determination of the cardiac output. When normal human values for the resting cardiac output obtained by the direct Fick procedure (5, 6) are divided into the normal human values for effective renal blood flow (7), the resulting effective renal fraction is about 19 to 20 per cent.

The present investigation was undertaken to make these measurements simultaneously in a series of normal subjects and in patients with essential hypertension, using the cardiac catheterization technique (8, 9) and the direct Fick principle for the measurements of the cardiac output.

METHODS

All studies were made during the morning at least 12 hours after the previous meal.

Effective renal blood flow was determined from the renal plasma clearance of p-aminohippurate or diodrast and from the hematocrit (10). At the same time, the glomerular filtration rate was measured by the renal plasma clearance of mannitol, inulin (10), or sodium

¹ This investigation was aided by a grant from the Commonwealth Fund.

⁵ Present address: Hospital of the Rockefeller Institute for Medical Research, New York City.

thiosulfate (11). In about two-thirds of the cases the effective tubular excretory mass was determined from the excretion at high plasma concentrations of p-aminohippurate (Tm_{PAH}) or of diodrast (Tm_D) (10, 12). Urethral catheterization with saline and air washout was employed routinely.

Mixed venous blood for oxygen analysis was obtained through a cardiac catheter introduced into the pulmonary artery, the right ventricle, or failing these, the right auricle. The exact position in the auricle was checked fluoroscopically immediately before or after sampling to assure optimal placement (5, 10). After insertion of the cardiac and bladder catheters and placement of the indwelling femoral arterial needle,⁶ a rest period of 30 minutes ensued, following which the patient was familiarized with the noseclip, mouthpiece, and with bedside procedure. Several trial collections of expired air were obtained prior to the definitive collection, in order to minimize anxiety and to prove the stability of the ventilation, respiratory and heart rates. Arterial and mixed venous blood were drawn simultaneously under oil during the two-minute collection of expired air. Blood oxygen contents were determined in duplicate by the method of Van Slyke and Neill (13). Oxygen consumption was calculated from gas analysis of the expired air by the Haldane method (13).

Shortly before and after the above procedure, the arterial pressure was recorded optically by the Hamilton manometer (14), or the mean pressure was read directly from a calibrated aneroid manometer connected to the arterial needle through a short rubber tubing containing air which damped the pressure pulse almost completely. In the former case, the mean pressure was calculated from the weight of a representative sample cut out carefully from the photographic record. In a few subjects the arterial pressure was determined by cuff sphygmomanometry, the mean pressure being estimated as $P_m = P_D + 0.4 (P_S - P_D)$. The total peripheral resistance was calculated by dividing the mean arterial pressure by the cardiac output per 1.73 sq.m. and is expressed as dynes cm^{-2} sec. (absolute unit).

The metabolic rate was calculated from the minute volume of oxygen consumed and the assumed R.Q. of

⁶ Specially designed by Becton, Dickinson and Company.

* Mean arterial pressure estimated from sphygmomanometer readings according to following formula: $P_m = P_d + 0.4(P_s - P_d)$.

† In the calculation of the effective renal fraction the first cardiac output from each study was taken.

‡ Results furnished by the courtesy of Dr. André Cournand and associates.

In columns 7 through 13 and 22 and 25 values are corrected to a surface area of 1.73 sq. m. In columns 16, 17 and 21 values are corrected to a surface area of 1.0 sq. m. Averages for columns 15 through 26 are calculated from values of first cardiac output determination.

0.82. The observed R.Q. was not used for this purpose because the short collection period makes the CO_2 value too dependent on variations in the respiratory pattern, and therefore not a reliable measure of metabolic CO_2 production. The values of ventilation rate and oxygen consumption are corrected to saturation at 37°C . and prevailing barometric pressure.

CLINICAL SUBJECTS

All subjects were patients of the Third (New York University) Medical Division of Bellevue Hospital. The normal subjects are representative of the convalescent ward population of a large city hospital. Most of them had had an upper respiratory infection or acute alcoholism. There was one each with a diagnosis of mild anxiety neurosis, headache of unknown cause and without neurological signs, central nervous system degenerative disease, mild chronic cholecystitis, old quiescent small lung abscess, and central nervous system syphilis. In addition, six patients, convalescent from traumatic or hemorrhagic shock, who were studied 17 to 76 days after injury, are included in the present series by the kind permission of Drs. André Cournand, D. W. Richards, Jr., and their co-workers (15, 16). None of the normal subjects had any evidence of cardiovascular or renal disease. All had been afebrile and all but two were ambulatory for at least a week prior to study.

Most of the patients with essential hypertension were admitted to Bellevue from the New York University Hypertension and Nephritis Clinic for the express purpose of study. None presented evidence of cardiac insufficiency.

RESULTS

Tables I and II present the data from each subject. The more pertinent data are presented in the form of frequency diagrams in Figures 1 and 2.

The control and hypertensive groups are fairly comparable with respect to distribution of hematocrit, metabolic rate and pulse rate. This is considered essential for the comparison of the other values, in so far as deviations from accepted normal standards in these three might be expected to affect cardiac output and renal function. The hypertensive group averages 7.5 years older, and contains a higher proportion of women than the control group. The two groups are reason-

ably comparable as regards nutritional status and general health exclusive of hypertensive disease.

The cardiac output, expressed as liters per minute per square meter of body surface area, averages 4.07 in the control group as compared to 3.97 in the hypertensive group. The difference is not significant. This is in accord with the observations of previous investigators (17, 18).

Mean arterial pressure is, of course, markedly higher in the patients with essential hypertension. Since the cardiac output is about the same in both groups, the average calculated total peripheral resistance is elevated in the hypertensive group to about the same extent as is the arterial pressure.

Effective renal blood flow is within the normal range of plus or minus twice the standard deviation from the respective male and female means (7, 12) in 17 and below in only one of the control subjects. Ten of the hypertensive patients have renal blood flow within the normal range; eight are below it, and none exceeds it. Moreover, in all but one of the hypertensive patients the values are less than the normal mean.

The effective renal plasma flow is within the normal range in all of the control subjects, whereas it is below this range in eight of the 19 hypertensives.

The filtration rate is below the normal range in one control subject and above in another. In the rest, it is well within the normal range. Among the hypertensives, 11 fall below the range and none exceeds the normal mean.

Seven of the nine determinations of TmPAH made in the control group fall in the normal range reported by Chasis, Redish, Goldring, Ranges and Smith (12), while five of the ten determinations in hypertensive patients lie below this range. Diodrast Tm , measured in five hypertensives, is in the normal range in four and below normal in one.

The filtration fraction (filtration rate/effective plasma flow) averages 0.190 in the control group and 0.221 in the hypertensive group. The difference between normal and hypertensive patients is less striking than that observed by Goldring and Chasis (10).

The effective renal fraction (effective renal blood flow/cardiac output) was calculated from the average effective renal blood flow and from

NUMBER OF SUBJECTS

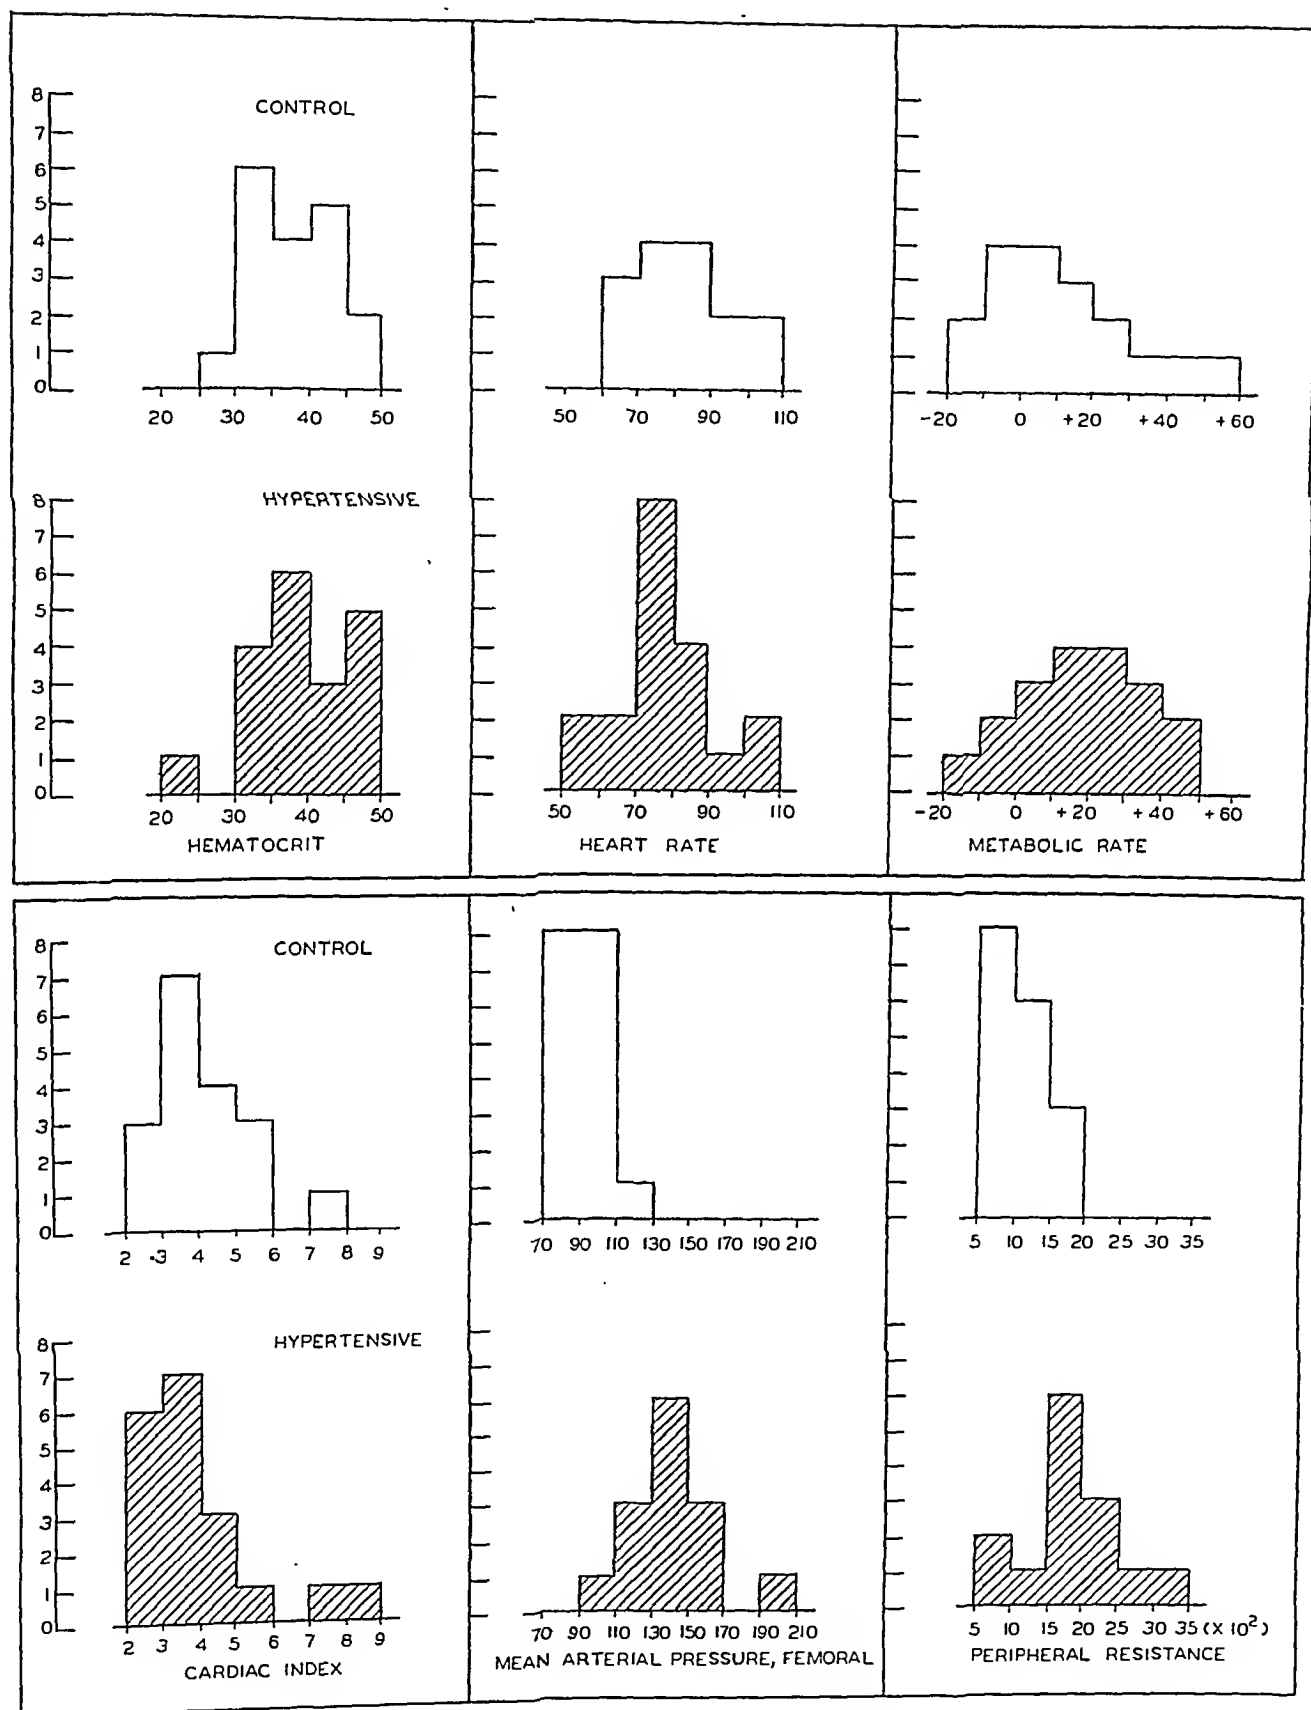

FIG. 1. FREQUENCY DISTRIBUTION OF OBSERVED PHYSIOLOGICAL VARIABLES IN CONTROL AND HYPERTENSIVE SUBJECTS

The values shown are those obtained in connection with the first cardiac output determination.

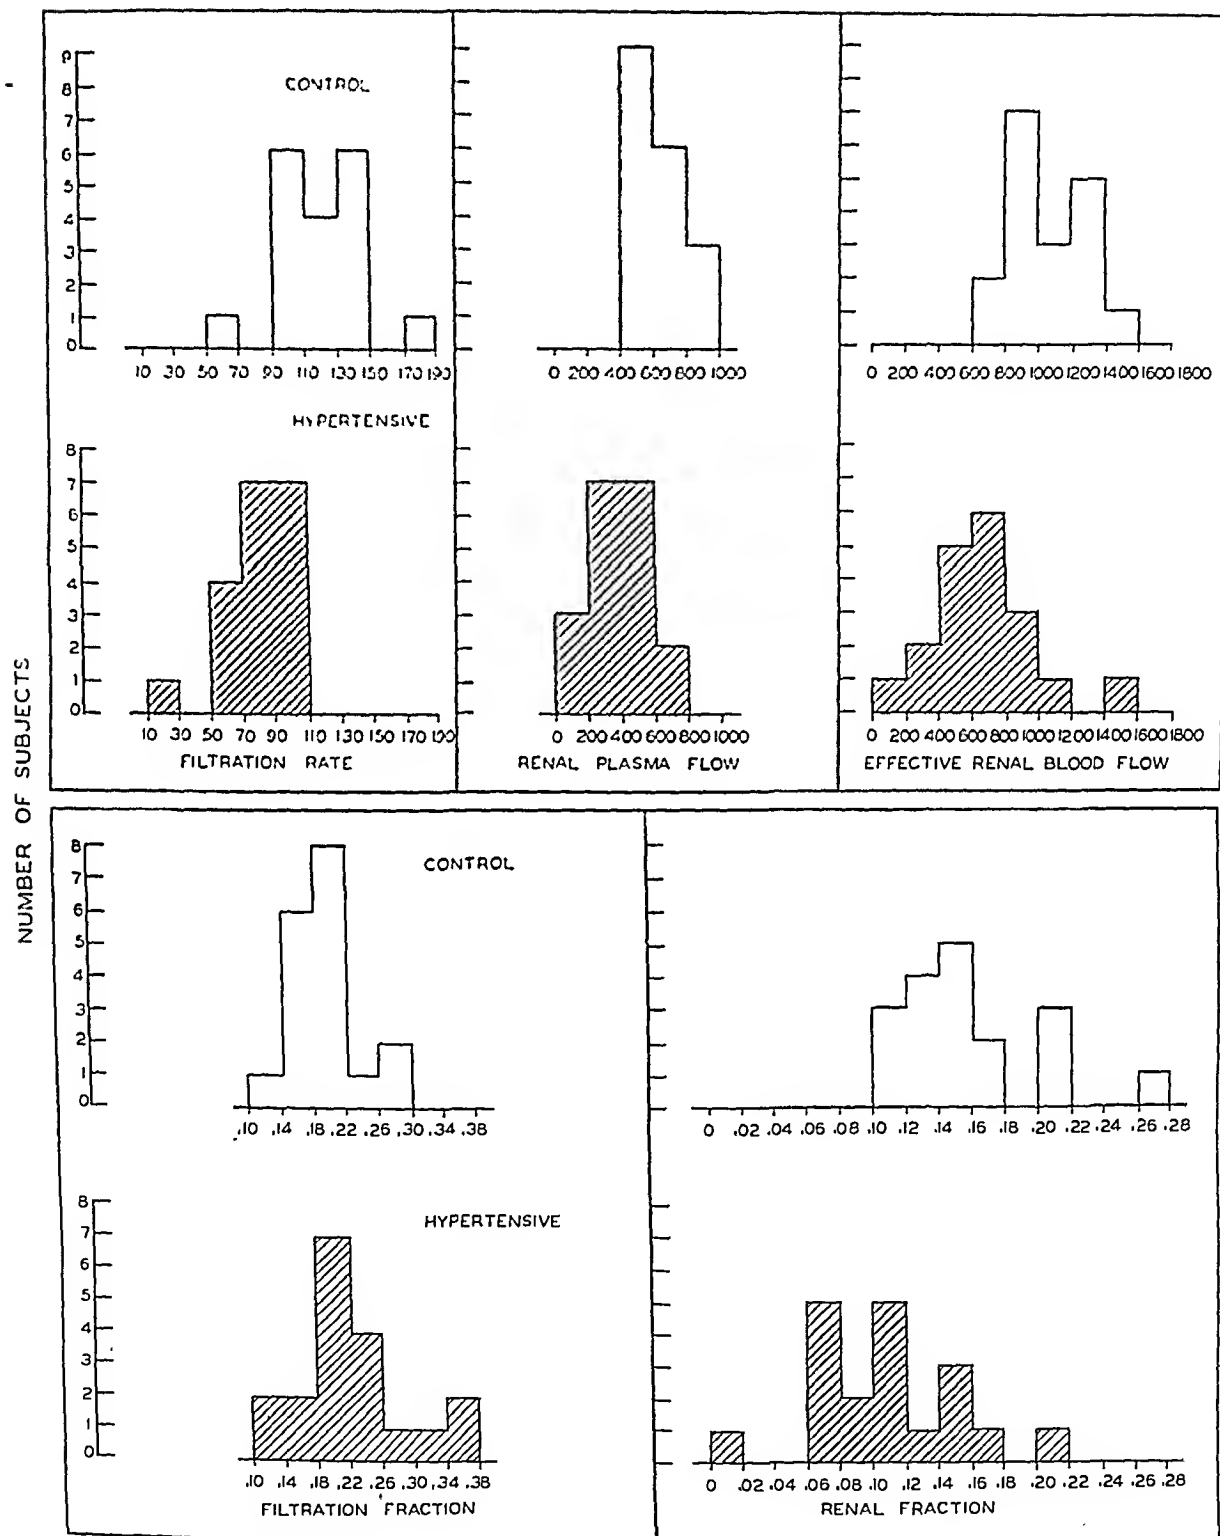

FIG. 2. FREQUENCY DISTRIBUTION OF OBSERVED PHYSIOLOGICAL VARIABLES IN CONTROL AND HYPERTENSIVE SUBJECTS

the first cardiac output determination on each individual. It varies from 0.102 to 0.269, with an over-all average of 0.156 in the control group. The corresponding range for the hypertensives is from 0.014 to 0.207, with an average of 0.106. This average figure of course has little meaning, since the renal blood flow must necessarily decrease with the progressive parenchymal destruction known to be associated with this disease, and if the cardiac output is maintained, the effective renal fraction will decrease correspondingly.⁷

DISCUSSION

As noted in the introductory paragraph, the normal effective renal fraction in the resting post-absorptive condition averages about 0.19 to 0.20 if the normal mean effective renal blood flow reported by Smith (7) is divided by the normal mean cardiac output reported by Cournand, Riley, Breed, Baldwin and Richards (5) and by Stead *et al.* (6).

The lower average of 0.156 for the effective renal fraction in the present control series may be due in part to the influence of moderate anemia on the renal blood flow of some of the subjects. Such a possibility would be suggested from the data of Bradley and Bradley (19). A more important factor, however, is the elevation of the cardiac output. From the data in Table I and from those of Brannon, Merrill, Warren and Stead (20) it would appear that anemia of the moderate degree encountered in these subjects does not, by itself, affect the cardiac output. On

⁷ It should perhaps be emphasized that the term "effective" renal blood flow indicates the volume per minute of blood perfusing functioning excretory tissue (22). On the same basis, "effective" renal fraction is defined as the fraction of the cardiac output which perfuses the functioning renal excretory tissue. If the renal extraction of p-aminohippurate is in the normal range of about 85 to 100 per cent (23, 24), the "effective" renal blood flow and "effective" renal fraction represent 85 to 100 per cent of the "total" renal blood flow and "total" renal fraction. If the extraction is less than normal, the relationship between the "effective" and "total" values will be correspondingly altered. Bradley (23) found that the extraction was normal in 12 of 14 cases of essential hypertension and was reduced only in two patients, both of whom had advanced renal disease with uremia. Judging from Bradley's data, it seems probable that the extraction is moderately or greatly reduced in M.B.I. Furthermore, it is possible that the extraction may be slightly to moderately decreased in M.D., T.V. and M. deL. (see Table II).

the other hand, anxiety, tenseness, annoyance, etc., which frequently complicate this type of investigation, would be expected to raise the cardiac output. This view is supported by the recent studies of Stead *et al.* (6), and of Hickam, Cargill and Golden (21).

It is believed that our control and hypertensive groups are reasonably comparable as regards anemia and anxiety, in so far as may be inferred from the hematocrit, metabolic rate and heart rate. Since the average cardiac output is the same in both groups, it is apparent that the decreased average effective renal fraction in the hypertensive group is attributable to the diminished effective renal blood flow known to accompany this disease.

SUMMARY

Results of simultaneously determined cardiac output by the direct Fick method and renal clearances are presented for 18 nonhypertensive and for 19 hypertensive subjects in the post-absorptive period at rest.

The cardiac indices of control and hypertensive subjects are within the same range, the average for each group being 4.07 and 3.97 liters, respectively.

The average effective renal fraction of the control subjects (0.156, range 0.102 to 0.269) is lower than that calculated from non-simultaneous determinations reported in the literature. This is believed to be a consequence of an increase in average cardiac output associated with the multiple manipulations of simultaneous study, and, to a lesser extent, of the moderate anemia of some of the subjects which may have led to some reduction in the effective renal blood flow.

An additional reduction in the effective renal fraction in the hypertensive subjects (average 0.106, range 0.014 to 0.207) results from the functional ischemia and progressive destruction of renal parenchyma characteristic of the disease, and in advanced hypertensive disease the effective renal fraction may be less than 0.020.

USE OF BLOOD DONORS WITH POSITIVE SEROLOGIC TESTS FOR SYPHILIS—WITH A NOTE ON THE DISAPPEARANCE OF PASSIVELY TRANSFERRED REAGIN

By MARK M. RAVITCH, THOMAS W. FARMER, AND BARBARA DAVIS

(From the Departments of Surgery and Medicine, The Johns Hopkins University and Hospital, Baltimore)

(Received for publication June 9, 1948)

Transfusion syphilis is not a serious problem with present methods of blood transfusion. In The Johns Hopkins Hospital there were 12 recognized instances of transfusion syphilis before 1939 (1). Since the establishment of the blood bank in that year, no such cases originating in this hospital have been recognized. With serologically tested blood available at all times, transfusion syphilis is no longer caused by the use of untested blood in conditions of dire emergency.

Of equal importance is undoubtedly the effect of refrigerator storage. With the advent of mass transfusions (6,000 to 7,000 donors are bled each year in The Johns Hopkins Hospital blood bank), and the employment of nurse technicians to bleed the donors, physical examination of donors has become impractical. Obviously, some donors must have given blood at a time when they had lesions of primary syphilis. It is accepted that some 30 per cent of such individuals are seronegative. It is from just such donors that 25 per cent of the cases of transfusion syphilis originated in the past (2). It can hardly be mere chance that we have observed no cases of transfusion syphilis since 1939. Refrigerator storage must be the responsible factor. In 1941 Turner and Discker (3) found that *Treponema pallidum* seeded in rabbit blood kept under conditions simulating those in the blood bank of The Johns Hopkins Hospital failed to give rise to infection when injected into rabbits after storage periods of 48 hours or longer. Bloch (4), simultaneously performing almost parallel experiments, found some persistence of infectivity up to 72 hours but none at 96 hours. Since most bank blood is three to four days old or older when used for blood transfusion and the experimental inoculations employed were much heavier than would be required to reproduce clinical conditions, it would appear that the absence of transfusion syphilis

since the establishment of the blood bank is at least partly attributable to refrigerator storage.

The possible infectivity of plasma has also been studied. Kolmer (5) found inoculated liquid plasma infectious after one and three hours of storage at 4–6° C. but not after 24, 48, or 72 hours. When serum inoculated with treponemes is frozen and desiccated, Turner, Bauer, and Kluth (6) found that under their experimental conditions infectivity of the spirochetes was completely destroyed. When inoculated plasma is frozen and held at –20° C. for 48 hours or longer, Ravitch and Chambers (7) found that the material is not infectious.

In civilian blood banks in areas where the incidence of syphilis in the population is high, as in Baltimore, large numbers of donors are rejected because of a history of syphilis or of anti-syphilitic treatment. Other donors are bled but their blood discarded because of a positive serologic test for syphilis.¹ In 1946, 1.2 per cent of white donors, 13.3 per cent of Negro donors, and 6.5 per cent of all donors—a total of 487 donors—at The Johns Hopkins Hospital, were found to have a positive STS and their blood discarded.

The evidence given above appears to be sufficient to indicate that with the use of plasma in any form (since it is necessarily held for bacteriologic culture for one week before release) there is no danger of transfusion syphilis. The importance of this in a military emergency is obvious. As far as concerns the danger of transmission of syphilis, no STS need be performed and no donor need be rejected in any plasma program. There remains only the problem of whether the passive transfer of reagin produces a positive STS in the recipient. To clarify this phase of the problem, plasma of known reagin titer was injected into individuals with a negative STS.

¹ Hereafter this is abbreviated to STS.

Less direct studies of the fate of passively acquired reagin of syphilis have been made by Fildes (8), Cruickshank (9), Dunham (10), and others (11). They observed that reagin was often passively transferred from the blood stream of women with positive STS to the circulation of their new-born infants. The majority of such infants, although not infected with *Treponema pallidum*, had positive STS at birth. Repeated quantitative STS in these infants showed a definite decline in the titer within seven days. The reactions were usually negative within 30 days, although in an occasional infant the passively transferred antibody could be detected for as long as 90 days. These observations represent passive transfer occurring in nature, analogous to the artificial transfusion of reagin-containing plasma into individuals with a negative STS. Recent studies by the technique of introduction of isotopic nitrogen into antibodies against type-specific pneumococci (12) show that the half-life of such an antibody molecule is approximately two weeks. There is no evidence of continued synthesis of passively transferred antibody.

METHOD

The subjects were all patients on the surgical service of The Johns Hopkins Hospital. At first only patients with known malignant disease were used, but as the results began to show the rapid return of the STS to negative, other types of patients were included. Sixteen patients with negative STS were studied.

All bottles of blood from donors with a positive STS were put aside in the refrigerator. As they accumulated, the plasma was drawn off and pooled, eight to ten donors contributing to each pool. The period of storage before centrifugation of blood and separation of plasma varied from one to ten days. The STS was titrated for each unit of plasma entering the pool and for each pool. The plasma pools were at once divided into units of 500 cc. and then frozen at -10° to -20° C. At intervals of two weeks to two months the frozen plasma was thawed in a water bath at 37° C. and 500 cc. administered intravenously to selected patients. The titer of the STS of each plasma unit after thawing was identical with the original titer. Specimens of blood were drawn from each recipient immediately before the plasma injection and at 24-hour intervals thereafter until the STS by all methods had become negative. In a few recipients several blood samples were taken during the first 24 hours.

Standard quantitative serologic tests were performed with the Mazzini technique (13), the Eagle flocculation (13), the Venereal Disease Research Laboratory Cardiolipin flocculation (14), and the Eagle Wassermann tech-

* D = doubtful.

nique (13). Sera were examined within 24 hours after they were drawn. In addition a portion of each serum was frozen at -10°C . In this way all of the specimens drawn from a given patient could subsequently be tested simultaneously after the last specimen had been drawn. Since the results obtained on retesting were practically identical with the original determinations, the results reported here are those obtained with fresh sera. The methods of reporting used by the respective authors of the tests were followed in determining the titers.

RESULTS

1. *Serologic titers of plasma pools.* The serologic titers of the five pools of plasma used in these studies are presented in Table I. In the preparation of pools No. 2 and No. 4 any plasma was used if the corresponding serum had a titer of 1 dilution unit or higher with the Eagle flocculation test. In the pooling of Nos. 8, 9, and 10, plasma was taken only from donors with a titer of 4 dilution units or higher with the Eagle flocculation test. As a result of this the serologic titers in these latter pools were higher. The titers of the pools of plasma varied from 4 to 128 dilution units with the various tests employed.

2. *Serologic titers in sera of recipients within the first 24 hours after the plasma infusion.* Blood specimens drawn from each of the 16 recipients within the first 24 hours after infusion gave positive or doubtful reactions in all cases. The indi-

vidual serologic titers varied from 1 to 32 dilution units in the various tests used (Table I).

3. *Progressive fall in serologic titer in relation to time.* In each case studied the quantitative serologic tests for syphilis gave the maximal response on the first day after infusion. On successive days after transfusion the serologic titers gradually fell in all cases until all serologic tests became negative. There was a rapid fall in titer within the first seven days. Fifteen of the 16 patients had serologic titers of 1 dilution unit or less on the seventh day. The sera of all the recipients became negative within nine to 19 days after injection, with minor fluctuations between tests (Table II). The fall in serologic titer of two of these patients is illustrated in Figures 1 and 2.²

4. *Later serologic follow-up of patients.* None of the patients developed clinical evidence of transfusion syphilis and all of those who could be followed for three to six months maintained their negative STS. Of the 16 patients to whom plasma was given, ten returned for examinations three to six months later and were found to have negative STS at that time. Four of the group had died of their original neoplastic processes, and two could not be found for follow-up examinations.

In reviewing the records of these patients it was found that all of them received penicillin at the time of their surgical procedures. The total dosages of penicillin ranged from 10,000,000 to 50,000,000 Oxford units over periods of seven to 20 days. So that, inadvertently, these patients received adequate treatment for incubating primary syphilis (15). Since under present clinical practice the vast majority of patients sick enough to require transfusions also receive penicillin, the

² While this study was in progress we had the opportunity to observe the effect of a transfusion of STS positive whole blood, erroneously administered. The donor's STS was positive in a titer of 16 dilution units (Eagle). The donor's blood had been stored for ten days at 5°C . The recipient had a negative STS on admission to the hospital. She was a pregnant woman, at term, transfused for secondary anemia. Six days after the transfusion with 500 cc. of STS positive blood her STS was positive (Eagle 2 units, VDRL Cardiolipin 4 units). Nine days after the transfusion all serologic tests were negative. Two days after the transfusion the patient was delivered of a normal infant. The baby's STS was negative when first determined on the ninth day of life.

FIG. 1. AFTER INJECTION OF 500 CC. OF PLASMA OF LOW TITER STS, THE RECIPIENT'S IMMEDIATE STS IS POSITIVE IN LOW TITER, AND AT TEN DAYS THE STS IS NEGATIVE BY ALL TESTS

FIG. 2. AFTER INJECTION OF 500 CC. OF PLASMA OF HIGH TITER STS, THE RECIPIENT'S IMMEDIATE STS IS POSITIVE IN HIGH TITER, AND IT REQUIRES 19 DAYS FOR THE STS TO RETURN TO NEGATIVE BY ALL TESTS

likelihood of the occurrence of transfusion syphilis is even further diminished.

DISCUSSION

The weights of the patients varied from 39 to 104 kg. (Table I). If one uses the figure of 45 cc. of plasma volume per kilogram of body weight (16), then the computed plasma volumes for these 16 patients ranged from 1,755 to 4,680 cc. To these initial volumes there was added 500 cc. of plasma containing reagin. It can be calculated that the antibody was diluted *in vivo* approximately one-fifth to one-tenth of its original titer. In the actual tests of the recipients' sera on the day following injection it was observed that one-fourth to $\frac{1}{32}$ of the original titer was found in the recipients' sera. It would appear, within the range of error involved in the computation and in the titration of the sera, that the antibody titer of the recipient after 24 hours represented the dilution of the injected reagin in the blood volume of the recipient.

All of the plasma used in this study was taken from blood of donors known to have a positive STS and preferably of high titer. Yet, even under these extreme experimental conditions, the positive STS in the recipient lasted less than three weeks in the longest instance and only four days in the shortest. If the STS positive blood normally discarded by the blood bank were converted to plasma together with all the STS negative blood usually processed into plasma, no pool would have more than one or two STS positive specimens in it. The resultant pool of plasma would have a very low titer of reagin and the duration of the persistence of the passively transferred positive STS, if any were detectable at all, would be correspondingly brief. In all probability no more than a doubtful reaction would be produced in the recipient.

It is experimentally proved that syphilis will not be transmitted by plasma desiccated or frozen under blood bank conditions. Liquid plasma stored at 4-6° C. one day or more is equally safe. We have now shown that the positive STS passively acquired by the recipient of a transfusion with STS positive plasma is of short duration. The blood of donors with syphilis in any stage should, therefore, be acceptable for use in the plasma program of any institution or organiza-

tion, in which plasma is desiccated, frozen, or refrigerated under the conditions noted above.

SUMMARY

1. Patients transfused with plasma from donors with a positive serologic test for syphilis will acquire a positive STS.
2. The initial titer of the acquired STS represents the dilution in the recipient's blood volume of the reagin contained in the injected plasma.
3. In all of 16 recipients the acquired positive STS had reverted to negative by the 20th day or before.
4. The blood of donors with syphilis should be acceptable for use in any blood bank with a plasma program, provided the material has been frozen, dried from the frozen state, or stored at least four days in the refrigerator.

HUMAN PROTHROMBIN: QUANTITATIVE STUDIES ON THE PLASMA LABILE FACTOR AND THE RESTORATIVE EFFECTS OF NORMAL, HYPOFIBRINOGENEMIC, AND HEMOPHILIC PLASMA ON THE PROTHROMBIN OF STORED PLASMA¹

By BENJAMIN ALEXANDER AND ANDRE DE VRIES,²
WITH THE TECHNICAL ASSISTANCE OF EUNICE ADDELSON

(From the Medical Research Laboratory, Beth Israel Hospital, and the Department of Medicine,
Harvard Medical School, Boston)

(Received for publication March 10, 1948)

In 1943 Quick (1) reported on the multiple nature of plasma prothrombin. On the basis of his data, which have been repeatedly confirmed (2-4), he concluded that prothrombin consists of two essential factors combined with calcium. The two components, "prothrombin A" and "prothrombin B," had different properties. The former was labile in oxalated or citrated plasma stored at refrigerator temperatures, not adsorbable by aluminum hydroxide, fairly heat stable, and not reduced in dicumarolized blood. Its deterioration was said to account for the high prothrombin time of stored plasma. "Prothrombin B," on the other hand, remained intact in refrigerated plasma, was removed by aluminum hydroxide, was labile at 60° C. for 15 minutes, and was decreased by the administration of dicumarol.

More recently other entities were described which affect the conversion of prothrombin to thrombin by thromboplastin plus calcium (5-7). These are apparently distinct from both "prothrombin B" and the factor which deteriorates in stored plasma. The term "prothrombin A" is now reserved by Quick (5) for one of these substances, and the term "labile factor" for the moiety which is found wanting in stored plasma. Normal prothrombin activity, as determined by the one-stage method, requires the presence of adequate amounts of all these substances.

Loomis and Seegers (4) found that the prothrombin activity of aged plasma could be restored remarkably by the addition of purified fibrinogen. Accordingly, they concluded that deterioration of fibrinogen accounts for lengthening of the prothrombin time in stored plasma and that "reactive

fibrinogen" is necessary for prothrombin activity by the one-stage technique. This conclusion is not in accord with those of Munro and Munro (8) and Honorato and Quick (9). The last authors (9) demonstrated that purified human fibrinogen was incapable of reactivating the prothrombin of stored human plasma. Furthermore, it has also been shown that plasma defibrinated by thrombin could reactivate the prothrombin (9, 10).

The availability of afibrinogenemic plasma from a subject with spontaneous fibrinopenia³ permitted decisive resolution of this conflict. It is the purpose of this report to present data supporting the evidence for the existence of a labile factor which is distinct from fibrinogen and whose deterioration as plasma ages accounts for the increasing prothrombin time. Also included are additional observations on the prothrombin activity of stored plasma and on the restorative effects of hemophilic plasma.

METHODS

Prothrombin activity was determined by the Quick method (11, page 312) with the following modification (12): Commercial (Difco) rabbit brain was used as the source of thromboplastin. Into each of many prothrombin-time tubes were pipetted 0.1-cc. aliquots of a uniform batch of freshly prepared thromboplastin, which were then stored at -10° C. until prothrombin determinations were made. Although thromboplastin thus kept frozen in ready-to-use units maintains full potency for eight months, new thromboplastin preparations were made every two weeks. The control prothrombin value, determined on normal plasma with each fresh batch, served as the control for the two-week period.

In some experiments the prothrombin time was determined on whole plasma unaltered or mixed with afibrinogenemic or hemophilic plasma. In others, the plasma or plasma mixtures were diluted with normal plasma ren-

¹ Supported by a grant from the Commonwealth Fund, New York.

² Aided by a fellowship from the Rothschild Hadassah University Hospital, Jerusalem.

³ We are indebted to Dr. W. Borges of the medical staff of the Children's Hospital, Boston, for generous cooperation in making blood from this patient available.

dered essentially free of prothrombin by prior adsorption with barium sulfate according to the technique of Rosenfield and Tuft (13). The prothrombin time of the diluted mixture was then determined. By comparing the values thus obtained with those of normal plasma diluted serially in the same manner actual prothrombin activities in per cent of normal were calculated.

Fibrinogen⁴ was measured by the method outlined by Quick (11, page 323). To 1.0 cc. of oxalated or citrated plasma were added 30 cc. of H₂O, 2.5 cc. of 0.02 M CaCl₂, and two drops of a saline solution containing 50 units of thrombin (Topical thrombin, Parke-Davis) per cc. After incubation at 37° C. for 15 minutes, the clot was wound on a glass rod, washed with physiological saline, hydrolyzed with sodium hydroxide and its tyrosine content determined. Since it is almost impossible to remove completely the fibrin clotted in stored plasma by winding on a glass rod, a technique was devised whereby the fibrin was filtered through glass wool, washed and then hydrolyzed in the usual manner. The procedure together with observations on changes in plasma fibrinogen during storage will be reported in detail in a subsequent communication (14).

Oxalated (1 cc. of 0.1 M sodium oxalate to 9 cc. of blood) or citrated (1 cc. of 2.5 per cent sodium citrate to 9 cc. of blood) normal blood was stored at 4-5° C. until its prothrombin time became prolonged. Sterile precautions were used and specimens were cultured to exclude bacterial contamination. Aliquots were then mixed with varying amounts of fresh normal, fresh or freshly frozen fibrinopenic, fresh hemophilic plasmas, or with fresh barium sulfated⁵ plasma, and prothrombin time determined.

RESULTS

Effect of BaSO₄ adsorption on plasma clotting constituents: The prothrombin time of BaSO₄ plasma exceeds 180 seconds, indicating a prothrombin activity of less than 1 per cent of normal. The question arises whether BaSO₄ removes important clotting constituents other than prothrombin. Although plasma so treated loses 100 mgm. of protein per 100 cc. (13) its fibrinogen concentration and antihemophilic potency were found unchanged. Also (see below) it is fully capable of rectifying the delayed prothrombin time of stored plasma. It is noteworthy that BaSO₄ removes far less prothrombin from citrated than from oxalated plasma.

Prothrombin activity of aged plasma and restorative ability of BaSO₄ plasma: The activity of normal oxalated plasma stored at 4-5° C. decreases to about 3 per cent of normal within three weeks

(Table I). Citrated plasma, on the other hand, deteriorates more slowly. These observations agree with those of Quick (15). At body temperature the loss is much more rapid although here, too, citrated plasma is more stable. Full restoration of the prothrombin activity to stored refrigerated plasma is induced not only by the admixture of fresh normal citrated or oxalated plasma (as found by others [1, 8]) but also by BaSO₄ plasma (Tables I, II). Substantial restoration to incubated plasma can similarly be obtained (Table I). Indeed, mixtures of fresh BaSO₄ plasma with oxalated plasma aged for more than 14 days at 4-5° C. exhibit much more prothrombin activity than the original plasma before, or within the first week

* Calculated on the basis of fresh normal plasma having 100 per cent prothrombin activity.

of storage despite the fact that the prothrombin time of the undiluted plasma has become very prolonged.

Prothrombin activity of congenital afibrinogenemic plasma and its restorative properties on prothrombin activity of stored plasma: As is evident in Table III, afibrinogenemic plasma from a patient with congenital afibrinogenemia can fully reactivate the prothrombin of stored plasma. This is all the more significant since a mixture of equal parts of both contains half the fibrinogen concentration of the stored plasma alone. Fibrinogen, therefore, is not the factor whose deterioration accounts for the retarded prothrombin time of stored plasma.

The afibrinogenemic plasma failed to clot following the addition of thromboplastin plus calcium. According to the orthodox one-stage method of determining prothrombin, this would be interpreted as indicating zero prothrombin. When, however, measured by the BaSO₄ plasma dilution technique its prothrombin activity was normal.

Relation between prothrombin activity and plasma fibrinogen concentration: The prothrombin time of mixtures of fresh normal plasma with congenital afibrinogenemic plasma or plasma defibrinogenated by the addition of thrombin does not change significantly until the fibrinogen drops to approximately 100 mgm. per cent (Table IV). Below this the prothrombin time increases until at 17-25 mgm. per cent the apparent prothrombin activity is about 11 per cent of normal. Furthermore, at this point the clot becomes translucent and coagulation is not abrupt. In three weeks old plasma (4-5° C.), on the other hand, prothrombin activity is about 3 per cent of normal but coagulation is sharp, the clot is opaque and fibrinogen concentration is well above 100 mgm. per cent (14). These observations also support the interpretation that deterioration of fibrinogen does not explain the elevated prothrombin time of stored plasma.

Prothrombin and prothrombin restorative activity of hypofibrinogenemic blood from a patient

* This plasma was citrated. All the others were oxalated. 1 cc. of this plasma to which was added 30 cc. of physiological saline, 2.5 cc. of 0.02 M CaCl₂ solution and two drops of thrombin solution (400 units per cc.) showed no clot within four hours.

† Stored 19 days at 4–5° C. Cultured and found sterile.

‡ The plasma which was stored for 19 days was then treated with barium sulfate to remove prothrombin activity.

§ Corrected for dilution.

with liver disease: In a patient with fibrinopenia⁶ and liver disease prothrombin activity as determined by the usual procedure was about 10 per cent of normal. When, however, prothrombin was measured on a mixture of the subject's plasma with prothrombin-free BaSO₄ plasma, higher but still subnormal prothrombin values were obtained. Clearly the BaSO₄ plasma provided a clotting agent, either fibrinogen, or other non-prothrombin substances, which was inadequate in the fibrinopenic plasma and which is necessary for full prothrombin activity. That normal prothrombin activity was not found in the mixture was to be expected in view of the extensive liver disease which this patient had (carcinoma of pancreas with diffuse involvement of the liver).

As with the congenital afibrinogenemic plasma, this fibrinopenic plasma lowered the elevated prothrombin time of stored plasma although not to the same degree as did normal plasma.

The effect of defibrination of plasma by thrombin on its ability to reactivate the prothrombin of stored plasma: We were able to confirm the ob-

⁶ Plasma fibrinogen concentration was 53 mgm. per 100 cc.

TABLE IV

Relationship between plasma fibrinogen concentration and prothrombin activity

* Assuming 250 mgm. per cent fibrinogen in the normal plasma. (This value was obtained on the same subject one month later.) The fibrinopenic plasma was shown to be completely devoid of fibrinogen but normal in prothrombin content.

servations of others (10, 16) that plasma defibrinated by thrombin can partially reactivate the prothrombin of stored plasma. That it cannot do so fully is perhaps due to some inactivation of labile factor by the prolonged incubation (one hour) required for complete defibrination and inactivation of whatever excesses of thrombin may have been present. Another possibility is partial removal of the labile factor by the fibrin clot.

The effect of heat defibrinogenation of plasma on its ability to restore prothrombin activity to stored plasma: Human plasma heated at 55½–56° C. for two minutes retains some prothrombin (27–40 per cent) but has lost its ability to reactivate the prothrombin of stored plasma. Although such treatment removes fibrinogen, the loss in prothrombin restorative ability was not referable to defibrination since adequate amounts of fibrinogen were provided in the mixture of heat-treated with stored plasma.

Can hemophilic plasma restore prothrombin activity to stored plasma? The admixture of hemophilic plasma to stored plasma resulted in complete reactivation of its prothrombin activity. The coagulation defect of hemophilic blood cannot therefore be attributed to deficiency in labile factor, which is in accord with the normal prothrombin activity in this disease.

Amount of labile factor necessary to reactivate the prothrombin of stored plasma: The reactiva-

tion of stored plasma prothrombin by progressively increasing admixtures of fresh plasma is shown in Table V. As the per cent of fresh plasma is increased, the prothrombin time decreases, but does not become normal until the mixture contains at least 50 per cent fresh plasma. It is noteworthy that up to 40 per cent the increment in prothrombin activity induced by the fresh plasma is practically equivalent to the absolute amount of prothrombin activity added with the fresh plasma. Above 40 per cent, relatively normal prothrombin times are approached which unfortunately cannot be accurately translated into prothrombin concentrations since they are in the least accurate range of the curve which relates prothrombin time to prothrombin concentrations.

Additional experiments (Table VI) were done in which increasing amounts of fresh plasma were added to stored plasma which had been incubated for 24 hours prior to the experiment. In this way, the labile factor of the stored plasma was completely destroyed whereas its "prothrombin B" was only partially inactivated. Similar mixtures were made using BaSO₄ plasma which was also incubated.

A sharp drop in prothrombin activity ensues when the amount of labile factor is decreased below 60 per cent of normal. Of interest, also, is the fact that a given deficiency of labile factor has a greater effect on prothrombin activity when the "prothrombin B" concentration is 50 per cent of normal than when it is normal.

It should be mentioned that the stored incubated plasma (Table VI) had no demonstrable fibrinogen. Nevertheless, the data are still valid, since amounts of fibrinogen requisite for substantial prothrombin activity are certainly provided by those mixtures containing at least 30 per cent of normal, or normal BaSO_4 plasma (see Table IV).

DISCUSSION

That afibrinogenemic plasma from a patient with spontaneous fibrinopenia is fully capable of reactivating the prothrombin of stored plasma is conclusive evidence that the restorative factor provided by fresh plasma is not fibrinogen. This is further substantiated by the restorative properties of normal plasma rendered fibrinogen-free by thrombin. Although restoration under the latter conditions was only partial, any reactivation by fibrinogen-free plasma excludes fibrinogen as being the restoring agent. The discordant results obtained with fibrinogen by Loomis and Seegers (4) are probably referable to contamination of their fibrinogen with labile factor.

Thus far the existence of labile factor is predicated upon observations that the prothrombin time increases as plasma ages although its prothrombin concentration does not change, and that this can be rectified by the admixture of whole fresh plasma, or plasma devoid of fibrinogen and prothrombin. This does not necessarily imply that it exists as an entity, albeit independent of these coagulation substances. It is conceivable that the above properties are referable to a particular configuration in the molecule of a plasma constituent distinct from fibrinogen and prothrombin, and essential for prothrombin activity as determined by the orthodox one-stage technique.

The prolonged prothrombin time of fibrinopenic plasma, of stored plasma, and of the plasma from recently described patients whose clotting defects were not referable to true hypoprothrombinemia (5, 17) demand reevaluation of the method for measuring prothrombin by the one-stage proce-

dure. Its inadequacies derive from the fact that in all these instances prolonged prothrombin times are observed despite normal prothrombin (B) concentrations. It is also pertinent to point out that the use of physiological saline as a plasma diluent in order to bring the prothrombin time into a range more suitable for accurate conversion into prothrombin content may aggravate these inadequacies by diluting, simultaneously with the prothrombin, other coagulation factors whose concentrations may already be critical. Clearly, these weaknesses of the one-stage technique can best be obviated by diluting the test plasma with plasma which has been rendered prothrombin-free in some manner and which still retains all other clotting factors. As far as is known, BaSO_4 plasma fulfills these criteria, although we are cognizant of the statement by Owren (6) that BaSO_4 removes some clotting "factor V" from plasma. (The exact amount of BaSO_4 required to do this is not indicated.)

Little is known regarding the exact quantitative relationships between labile factor concentration and apparent prothrombin activity. Munro and Munro (18) claim that there is practically no change in prothrombin time over a wide proportion of labile factor and "prothrombin B" and that a deficiency of one component can be partially compensated for by an excess of the other (3). This is not entirely in accord with our finding.

Thus far no case is recorded in which a deficiency of labile factor has been observed. It appears that reducing it below 50 per cent of normal can result in substantial prolongation of the prothrombin time. The experiments on our patient with extensive liver disease suggest that this subject was somewhat deficient not only in prothrombin and fibrinogen, but also in labile factor since his plasma could not completely reactivate stored plasma prothrombin. That this cannot be referable to low fibrinogen concentration is clear from the quantitative relationships between fibrinogen concentration and prothrombin time (Table IV). It is possible that with a more practical technique for labile factor determination such as that of Stefanini and Quick (16) more patients will be found with coagulation defects related to insufficiency of this entity.

Our observations on the heat sensitivity of labile factor are not in accord with those of Quick

(1), who claimed that it is fairly heat stable. In our experience, the labile factor is quite rapidly inactivated at body temperature, and completely destroyed at $55\frac{1}{2}$ – 56° C. within two minutes, which agrees with the finding of Honorato (10). Under these conditions "prothrombin B" is more stable.

The reason why BaSO_4 does not remove all the prothrombin from citrated (in contrast to oxalated) plasma is obscure. In this connection it also is noteworthy that aluminum hydroxide adsorbs prothrombin less effectively from heparinized than from oxalated plasma (1).

The enhanced prothrombin activity of plasma stored for more than two weeks (when determined with BaSO_4 plasma as diluent) is striking and cannot at present be explained. Honorato (10) similarly found that a mixture of stored plasma with fresh plasma treated with $\text{Al}(\text{OH})_3$ shows more prothrombin activity than the fresh plasma alone. He attributes this to qualitative changes in fibrinogen consequent to storage which renders it more easily coagulable. Experiments which will be presented in a subsequent communication (14) indicate that this cannot be the explanation since the fibrinogen of stored plasma becomes progressively less coagulable while at the same time the prothrombin activity, when measured by the BaSO_4 plasma dilution technique, increases. It is unlikely that more prothrombin can develop as plasma ages. Furthermore, no such increase in prothrombin is found by actual isolation or when the two-stage technique for prothrombin determination is used (19). It is possible that a naturally occurring clotting inhibitor (20) disappears as plasma is aged.

CONCLUSIONS

1. The prothrombin activity of stored plasma as determined by the one-stage technique can be fully reactivated by the admixture of fresh normal plasma, congenitally afibrinogenemic plasma, BaSO_4 plasma (prothrombin-free) or hemophilic plasma. The restorative factor (labile factor) is not fibrinogen.

2. The prothrombin time of plasma can be greatly influenced by alterations in the concentrations of (a) prothrombin, (b) labile factor and (c) fibrinogen.

3. Prothrombin-free BaSO_4 plasma has a normal amount of labile factor, fibrinogen, and anti-hemophilic activity. Its use as a diluent in measuring prothrombin by the one-stage technique is advantageous since in this way these non-prothrombin variables are adequately controlled.

4. Plasma stored for more than two weeks shows enhanced prothrombin activity when measured by the BaSO_4 plasma dilution technique. The explanation of this phenomenon is obscure.

A STUDY OF THE RATE OF DISAPPEARANCE OF A DIGITALIS GLYCOSIDE (LANATOSIDE C.) FROM THE BLOOD OF MAN¹

BY MEYER FRIEDMAN AND RENÉ BINE, JR.

(From the Harold Brunn Institute for Cardiovascular Research, Mount Zion Hospital, San Francisco)

(Received for publication June 30, 1948)

INTRODUCTION

Exact quantitative determinations of either digitalis or its derivatives in the blood of patients or animals receiving these drugs have never been accomplished. The prime difficulty of course has been the inability to detect relatively minute amounts of digitalis or allied cardiotonic drugs in body fluids. Because of the absence of such quantitative data, very little is known about the actual fate in the body of either ingested or injected digitalis substances.

In previous studies (1, 2) we were able to detect by means of the embryonic duck heart preparation extremely minute amounts of a digitalis glycoside (Lanatoside C.) in both Tyrode's solution and in human blood. Moreover, the quantity of glycoside detectable (less than a microgram per cubic centimeter of blood) by this means suggested the possibility that the blood of patients receiving Lanatoside C. might be assayed for its glycoside content.

Accordingly, blood samples of ten patients who had received intravenously a therapeutic quantity of Lanatoside C. were assayed. It was found possible not only to detect in a quantitative fashion the presence of glycoside in such samples but also to measure the rate of the drug's disappearance from the blood stream.

METHODS

A. Quantitative detection of Lanatoside C. in human serum (*in vitro*)

In a previous study (2) it was found that the embryonic duck heart exhibited a "digitalis effect" (the occurrence of A-V block, missing beats or marked retardation of beating) when immersed in human serum containing 0.10 μ g. or more of Lanatoside C. per cc. Furthermore, it was observed that the time necessary for

the occurrence of the "digitalis effect" varied inversely with the amount of glycoside present in the serum samples. Finally, it was observed over a period of 20 months that no temporal variation occurred in the sensitivity of these embryonic hearts to a given concentration of Lanatoside C. These last findings offered the possibility of a method for the quantitative detection of glycoside.

Accordingly, different but known amounts of Lanatoside C. were added (0.10 to 1.0 μ g. per cc. of serum) to samples of human serum and the various samples were refrigerated for 24 hours. Then five embryonic duck hearts were added to each sample and the individual times elapsing before occurrence of the "digitalis effect" were observed. This procedure was repeated until over 20 hearts had been exposed and observed in at least four different samples of serum containing the same concentration of glycoside. From these data, it was possible to construct a table whereby the quantity of Lanatoside C. in any serum sample could be determined by observation of the average time taken for five or more embryonic hearts to exhibit a typical "digitalis effect."

B. Quantitative detection of Lanatoside C. in the patients' sera

Serum samples were obtained from ten patients (seven of whom were suffering from either right or left congestive heart failure) who had not received any type of digitalis therapy within three months. To 1 cc. samples of each patient's serum, 0.10, 0.15 and 0.20 μ g, respectively, of Lanatoside C. were added. These samples together with one not containing glycoside were refrigerated for 24 hours and then each was tested on five embryonic hearts. The embryonic hearts were found to beat normally for at least 80 minutes in the control serum samples of each patient. Furthermore, the times elapsing for the occurrence of "digitalis effect" in hearts immersed in the various glycoside-serum samples corresponded in every case to the times previously observed for the same concentrations of Lanatoside C. as listed in the standard table. It was considered, therefore, that the serum of each of these patients was satisfactory for the quantitation by the duck heart method of possible Lanatoside C. content.

Approximately 1.6 mgm. of Lanatoside C. were given by vein over a period of three minutes to each of the ten patients. Blood samples (10 cc.) were obtained from the vein of the opposite arm immediately after the injection of the glycoside and again after 7½, 15, 22½ and 30

¹ Aided by grants from the Life Insurance Medical Research Fund, the U. S. Public Health Service, and The Sandoz Chemical Works.

minutes. In several instances, samples also were taken at later intervals.

The blood samples were allowed to clot, the serum was removed and stored in the ice box for 24 hours. Six embryonic hearts then were added to two portions of each serum sample and the individual times elapsing before the occurrence of "digitalis effect" in each heart was noted exactly as described previously (1, 2). The time periods were averaged and compared to the standard table correlating the time elapsing before occurrence of "digitalis effect" in the embryonic hearts with the concentration of Lanatoside C. per cc. of serum. If a sample did not cause a "digitalis effect" within a period of 80 minutes, it was assumed, because of the previous study with known concentrations, that the sample contained less than 0.1 μ g. of glycoside per cc. of serum. Therefore 0.1 μ g. of the drug was added to 1 cc. of the same sample and tested again. If then the average time elapsing before occurrence of "digitalis effect" was the same as that occurring in samples known to contain 0.1 μ g. per cc. it was assumed that the unknown sample contained less than 0.05 μ g. per cc. If, on the other hand, such a sample caused the appearance of the "digitalis effect" in a time period equal to or shorter than that previously observed in samples containing 0.15 μ g. per cc. it was concluded that the unknown sample contained at least 0.05 μ g. per cc. In this manner, 0.05 μ g. of Lanatoside C. per cc. of serum could be detected.

RESULTS

A. The quantitative detection of Lanatoside C. in human serum (in vitro)

As Table I demonstrates, serum samples containing concentrations of Lanatoside C. differing for the most part by only 0.1 μ g. per cc. could be

quantitatively differentiated from each other by observation of the time of occurrence of "digitalis effect." The standard error of the mean of the values observed at any concentration was small enough to allow such quantitation except when concentrations of 0.8 μ g. or more of glycoside per cc. of serum were present. These latter concentrations, however, were never reached in the blood of patients receiving therapeutic amounts of Lanatoside C.

B. The quantitative detection of Lanatoside C. in patients' sera after its intravenous injection

As Table II indicates, the serum of each of the patients contained a detectable amount of Lanatoside C. immediately after the intravenous administration of 1.6 mgm. The average concentration of the glycoside was 0.25 μ g. per cc. of serum (Range: 0.20 to 0.40). No significant difference was found in the serum concentration of the drug in patients with or without congestive failure.

The initial concentration of the glycoside, however, was not maintained for when nine serum samples obtained 7.5 minutes after administration of the drug were assayed, it was found that the average concentration of Lanatoside C. had fallen to 0.10 μ g. per cc. of serum (Range: 0.05 to 0.15). At the end of 15 minutes, no glycoside could be detected in the sera of two of the ten patients. The sera of the remaining patients contained only 0.05 to 0.15 μ g. per cc. At the end of 22.5 minutes, only two of eight patients tested still contained a detectable amount of Lanatoside C. in their blood (0.05 to 0.10 μ g. per cc.). At the end of 30 minutes, no Lanatoside C. (i.e., less than 0.05 μ g. per cc.) could be found in the sera of nine of the ten patients. At the end of an hour, no glycoside was detected in the sera of the four patients tested. Finally the sera of two patients who exhibited signs of digitalis intoxication at the time the 24-hour sample was taken, 24 hours after injection did not contain a detectable amount of Lanatoside C.

DISCUSSION

The quantitative detection of Lanatoside C. in the blood of a patient or animal treated with this drug allows the future possibility of studying the fate of other digitalis glycosides in the human or

‡ ND indicates that no Lanatoside C. could be detected in serum sample.

animal body. Little is known at present about this matter.

The present study has resulted not only in a quantitative estimation of the actual amount of Lanatoside C. in the blood of a patient immediately after the intravenous administration of the drug but even more important, has allowed us to determine its rate of disappearance from the blood stream.

In a previous study (2) it was found that when this particular glycoside was added to whole blood, little or none was adsorbed or contained in the blood cells. Therefore, the rapid disappearance of Lanatoside C. from the serum of our patients (usually over 80 per cent within 22.5 minutes after administration) could not be explained by its entrance into or adsorption by blood cells. Nor could the rapid disappearance be due to inactivation of the Lanatoside C. by serum, which was found in the previous study to be unable to do so (2). Also, in view of the fact that the plasma proteins were not able to adsorb this particular glycoside (2), it seems most likely that the rapid disappearance of Lanatoside C. from the blood stream was due to its actual escape therefrom by the simple process of diffusion.

It is perhaps worthy of note that the rate of disappearance of the drug from the blood stream did not appear to be affected by the presence or absence of congestive heart failure. It is interesting too that two patients experienced symptoms of

digitalis intoxication 24 hours after administration of Lanatoside C., at which time none of it could be detected in their blood.

SUMMARY

1. The quantitative detection of small amounts of Lanatoside C. in human serum was accomplished.
2. The rate of disappearance of this glycoside from the blood of ten human subjects after its intravenous administration was observed.
3. The probable reason for the rapid disappearance of Lanatoside C. from the blood stream of the experimental subjects was discussed.

THE RENAL REGULATION OF ACID-BASE BALANCE IN MAN. III. THE REABSORPTION AND EXCRETION OF BICARBONATE¹

BY R. F. PITTS, J. L. AYER, AND W. A. SCHIESS
WITH THE TECHNICAL ASSISTANCE OF PHYLLIS MINER

(From the Department of Physiology, Syracuse University College of Medicine, Syracuse, N. Y.)

(Received for publication January 26, 1948)

In the normal individual the concentration of bicarbonate in the extracellular fluid is maintained within limits of 24 and 28 mM per liter despite wide variations in the intake of acid and base forming foodstuffs. Stabilization of level depends on continuously operative renal mechanisms, for although carbonic acid is continuously available, no large reserve depots of base exist upon which the body may draw when circulating stores are depleted, or to which the body may consign an excess in times of abundance. The renal problem of regulating the concentration of bicarbonate may be outlined in the following terms: 1, conservation of those stores which normally enter the renal tubules in the glomerular filtrate; 2, excretion of any excess present in the body; and 3, conversion of the salts of fixed acids into bicarbonate to replenish depleted body stores.

These aspects of regulation have been studied in normal human subjects at plasma bicarbonate levels ranging from 13 to 39 mM per liter. It has been observed at plasma concentrations below 24 mM per liter that essentially all of the filtered bicarbonate is reabsorbed; negligible quantities are lost in the urine. Above 28 mM per liter a relatively constant quantity is reabsorbed, amounting on an average to 2.8 mM per 100 ml. of glomerular filtrate; any excess present in the filtrate is excreted. These properties of the reabsorptive mechanism would in themselves assure stabilization of plasma level were there no continuous drain on bicarbonate stores for purposes of neutralizing fixed metabolic acid. Because such a drain exists in the individual maintained on the usual acid ash diet, the renal tubules must split neutral salts of the glomerular filtrate, restoring the fixed base to the body as bicarbonate, and eliminating the unwanted anions either as free titratable acid or in combination with ammonia.

Within limits these processes of replenishment proceed at rates proportional to the degree of depletion of the alkali reserves. The data upon which these findings are based are reported below.

METHODS

Fourteen experiments were performed on three healthy male subjects in the post-absorptive state. Adequate hydration was assured by the ingestion of two to four glasses of water at the start of each experiment. In some experiments plasma bicarbonate was reduced by the ingestion of 5 to 20 gms. of ammonium chloride on the preceding day. In all experiments plasma bicarbonate was elevated by the intravenous infusion of 1.5 to 3.0 per cent sodium bicarbonate at rates of 5 to 13 ml. per min. The thiosulfate clearance was used as a measure of glomerular filtration rate (1, 2).

Urine was collected with special precautions to avoid loss of carbon dioxide. One subject, who could empty the bladder completely of even small volumes of urine, voided into a funnel connected with a rubber tube dipping beneath oil. A close fit between funnel and glans minimized exposure of the urine to air. The other two subjects were catheterized and the catheter was extended under oil by attaching to it a length of rubber tubing. The urine was permitted to drain continuously through the catheter and at the end of the collection period the bladder was emptied by voluntary effort and abdominal compression. The customary procedure of washing out the bladder and introducing air at the end of each urine collection was avoided because of the error it causes in the determination of urinary carbon dioxide tension. Although more constant clearances were obtained in the subject who voided spontaneously, the similarity of carbon dioxide tensions in urine samples collected by the two methods, as well as the stability of tension for some six to eight hours after collection, indicated that both methods adequately protected against carbon dioxide loss. Arterialized venous blood was drawn and analyzed by methods described in a previous communication (3).

RESULTS

The reabsorption and excretion of bicarbonate as a function of plasma concentration

Two illustrative experiments on a single subject are presented in Table I; the first two clear-

¹ Aided by grants from the United States Public Health Service and the John and Mary R. Markle Foundation.

ance periods of each experiment constitute control observations made prior to the infusion of bicarbonate. Sufficient ammonium chloride had been ingested on the day preceding Experiment 1 to reduce the plasma bicarbonate concentration to 13.4 mM per liter, pH to 7.27, and partial pressure of carbon dioxide to 30.5 mm. Hg in the initial two periods. The urine was acid in reaction and contained negligible quantities of bicarbonate. The quantity of bicarbonate filtered each minute was calculated by multiplying the plasma concentration, expressed in mM per ml., by the glomerular filtration rate in ml. per min. The quantity excreted was calculated by multiplying the urine concentration, expressed in mM per ml., by the rate of urine flow in ml. per min. The quantity reabsorbed is equal to the difference between the quantities filtered and excreted. It is evident that under conditions of moderately severe acidosis over 99.99 per cent of the filtered bicarbonate was reabsorbed; only a negligible trace was excreted.

Following the control periods of Experiment 1, the plasma concentration of bicarbonate was gradually raised from 13.5 to 18.4 mM per liter by the infusion of bicarbonate, the reaction of the plasma

returning to a normal value, namely pH 7.38. In consequence of the increase in plasma concentration and the increase in filtration rate, the quantity of bicarbonate delivered into the renal tubules rose from 1.34 to 2.12 mM per min. Reabsorption of the filtered bicarbonate was essentially complete throughout this range. Likewise in Experiment 2 at a somewhat higher control level, reabsorption was equally complete. However, as the plasma level was raised to or above 25.8 mM per liter, the renal tubules failed to reabsorb all of the bicarbonate presented to them, and significant quantities appeared in the urine.

It is apparent from the two experiments presented in Table I that the rate of reabsorption of bicarbonate increased in direct proportion to the increase in plasma concentration; *i.e.*, reabsorption increased from 1.34 to 3.80 mM per min. as plasma concentration rose from 13.4 to 38.2 mM per liter. However, there occurred coincidentally an increase in glomerular filtration rate, and since previous work on the dog (3) has shown that the tubular capacity to reabsorb bicarbonate at any given plasma level varies in proportion to filtration rate, the data were calculated in terms of mM reabsorbed per 100 ml. of glomerular filtrate. It is

FIG. 1. THE REABSORPTION AND EXCRETION OF BICARBONATE AS A FUNCTION OF PLASMA LEVEL

evident from Table I that bicarbonate reabsorption expressed in this fashion increased with plasma concentration up to a plasma level of 27.6 mM per liter. From 27.6 to 38.2 mM per liter reabsorption was essentially constant, varying only from 2.63 to 2.79 mM per 100 ml. of filtrate.

In Figure 1 are presented the massed data derived from 14 experiments on three subjects. The reabsorption and excretion of bicarbonate, expressed in mM per 100 ml. of glomerular filtrate, are plotted against plasma bicarbonate concentration. It is evident that reabsorption of filtered bicarbonate was essentially complete at plasma levels below 24 mM per liter. Above 28 mM per liter gross excretion occurred, and reabsorption was limited to an average value of 2.8 mM per 100 ml. of glomerular filtrate (varying within limits of

2.6 and 3.0 mM). Thus the renal plasma threshold² for bicarbonate in this series of experiments varied only within narrow limits of 25 to 27 mM per liter. It must be emphasized that this threshold probably holds exactly only under our experimental conditions of polyuria, acutely elevated bicarbonate concentration, and otherwise normal plasma electrolyte pattern.

Interaction in the reabsorption of chloride and bicarbonate

The ingestion of ammonium chloride converts a portion of the circulating store of bicarbonate into chloride, the increase in the latter roughly equaling the decrease in the former. In diarrhea

² Renal threshold is used in the sense of that plasma concentration above which significant excretion occurs.

FIG. 2. THE RELATIONSHIP BETWEEN BICARBONATE CONCENTRATION AND pH IN 82 SPECIMENS OF URINE SO COLLECTED AS TO PREVENT LOSS OF CARBON DIOXIDE

The smooth curve was calculated from the Henderson-Hasselbalch equation assuming a constant $p\text{CO}_2$ of 50 mm. Hg.

STUDIES IN DIABETIC ACIDOSIS AND COMA, WITH PARTICULAR EMPHASIS ON THE RETENTION OF ADMINISTERED POTASSIUM

By T. S. DANOWSKI, J. H. PETERS, J. C. RATHBUN,
J. M. QUASHNOCK, AND L. GREENMAN

(From the Departments of Research Medicine and of Physiological Chemistry, the Children's and Presbyterian Hospitals, and the Reuzichausen Foundation, University of Pittsburgh, School of Medicine, Pittsburgh)

(Received for publication July 22, 1948)

Abnormally low concentrations of potassium, at times associated with muscular paralysis, have been observed in the serum of diabetic patients while under treatment for acidosis or coma (1-4). Available data indicate that deficits of cell potassium are also present in at least some of these subjects (5). In an attempt to characterize and quantitate the magnitude of these deficits, exchanges of water, electrolytes, carbohydrate, and protein have been investigated in diabetic acidosis and coma prior to, during, and following the administration of potassium salts.

EXPERIMENTAL PROCEDURE AND METHODS

Eight cases in all have been studied. Of these, two were adults and the remaining six juvenile diabetics 16 years of age or younger. On admission all had Kussmaul breathing, a marked reduction of the serum bicarbonate content, hyperglycemia, glycosuria, and ketonuria.

Studies during treatment and recovery were divided into three periods. The first or pre-KCl period extended from admission to the point where the patients had improved sufficiently to be maintained on an oral intake. During this time insulin, 0.9 per cent saline, and, once the blood sugar began to drop, glucose solutions were administered in amounts summarized in Table I. Under this treatment ketosis diminished, overbreathing ceased, hyperglycemia decreased, and mental clarity returned. This interval lasted 12 to 25 hours in the individual subjects. During the second or KCl period, 22 to 37 hours in length, the patients received insulin, 10.0 to 30.0 grams of KCl *per os* or intravenously, whole milk containing added carbohydrate, and water as desired. The third or post-KCl period began after the final dose of KCl and lasted up to 34 hours. During this time the patients received insulin as needed, together with measured amounts of water and milk.

In all subjects concentrations of the whole blood non-protein nitrogen, blood sugar (6-8), and the levels of serum chloride, bicarbonate, sodium, potassium and water were measured at the beginning and end of each period (6, 9-12). Average values for the electrolyte, carbo-

hydrate, and protein content of fresh milk have been used in calculating the intake (13, 14). Urine excreted during each period was analyzed for nitrogen, sodium, potassium, chloride, and glucose (6, 10, 11, 15, 16). Body weight was determined when possible at the start and end of each period.

METHOD OF CALCULATION

Alterations in extracellular fluid volume were calculated from changes in the chloride space, based on the external balance of this anion and corrected for changes in the serum concentrations of chloride as described by Elkinton and co-workers, and by Darrow (17-19). In view of the dehydration known to develop in the course of diabetic acidosis and coma, the initial extracellular volume was assumed for purposes of this calculation to be 15 per cent of the body weight rather than the usual value of 18.7 to 23 per cent found in non-dehydrated human subjects (20). In two instances a pre-treatment weight could not be obtained. A reasonable assumption was therefore made as to its magnitude, based upon subsequent weights and the balance of water. The volume of the chloride space and the concentrations of sodium and potassium in extracellular water, corrected for the Donnan effect, were used in the calculation of increments and decrements of these ions in extracellular fluid. The retention of sodium and of potassium by cells was taken to be the difference between the intake of these cations and the amounts retained in extracellular fluid plus those excreted in urine. In the case of potassium the final values recorded include corrections for the balance of cellular nitrogen, using the K:N ratio of 2.38 m.eq.:1.0 gm. N. In determining the balance of cellular nitrogen changes in the concentration of the nonprotein nitrogen have been taken into account, assuming for this purpose that the nonprotein nitrogen is distributed uniformly through all of the body water, and that 0.65 of the body weight is water. Similar treatment of the sodium data does not, of course, significantly affect the balances of this electrolyte because of the low Na:N ratio in cells. The data on cell base in Table III represent, therefore, balances in excess of the sodium and potassium which move with nitrogen in the anabolism and catabolism of protein.

RESULTS

A. Alteration in serum water and in extracellular volume

On admission a variable degree of plasma dehydration, as measured by the water content, was present (Table II). The values ranged from 897 to 924 gms. of water per liter of serum in contrast to levels of 922 to 938 gms. per liter ordinarily found in healthy adults (21). There is no means of deciding how much of the deficit in any particular patient should be assigned to losses of body fluid alone, and how much is to be considered secondary to a disappearance of circulating plasma proteins of the type observed during depletion of body water and solutes (22, 23). At the end of the first period of treatment all serum water values were again in the normal range, or actually above it. No consistent pattern is apparent in the fluctuations in serum water during the second and third treatment periods.

The expansion in the chloride space uniformly

observed in each patient at the end of the first treatment period suggests that considerable deficits of extracellular water as well had been incurred prior to admission (Table III). These increments, as calculated from the chloride space, ranged from +1.0 to +9.5 liters. Since subsequent changes in Periods II and III of each study in no instance entirely cancelled this initial expansion it is reasonable to interpret this persistent positive balance of extracellular water as indirect evidence suggestive of extracellular dehydration on admission. On the other hand, it is likely that in at least some of the subjects the extracellular fluid volume had been overexpanded, even though edema did not develop. This appeared to be true in some of the infants with diarrhea treated by Darrow (19).

B. Serum electrolyte concentrations prior to and during therapy

1. *Sodium and chloride:* Despite these deficits of body water it is to be noted that the concen-

FIG. 3. LEFT: THE RELATIONSHIP BETWEEN THE $p\text{CO}_2$ OF THE URINE AND THE $p\text{CO}_2$ OF THE PLASMA
 RIGHT: THE RELATIONSHIP BETWEEN THE $p\text{CO}_2$ OF THE URINE AND THE REABSORPTION OF BICARBONATE

a similar disturbance of electrolyte pattern results from the loss of alkaline intestinal secretions (4, 5). In contrast in pernicious vomiting, loss of chloride is attended by a compensatory elevation of plasma bicarbonate (4, 6, 7). Thus there exists an inverse relationship between the plasma concentrations of chloride and bicarbonate, whereby the sum of the two is maintained relatively constant. Under conditions of stress, the kidney, failing to maintain the normal anion pattern, at least approximates maintenance of constant total anion (hence cation) concentration. As illustrated in Experiment 2 of Table I, this appears to result from compensatory changes in the quantities of chloride and bicarbonate reabsorbed, when one is presented to the renal tubules in excess. Thus 10.46 mM of chloride were reabsorbed per 100 ml. of glomerular filtrate at a plasma bicarbonate concentration of 20.4 mM per liter. As the bicarbonate level was raised the reabsorption of chloride fell and the excretion rose. The sum of chloride and bicarbonate reabsorbed, however, remained roughly constant.

The acid-base equilibrium of the urine

When an excess of base is liberated in the body in consequence of the metabolism of an alkaline ash diet, it is converted to bicarbonate and excreted in the urine. Gamble (8) and Marshall (9) have shown that the carbon dioxide tension of the urine roughly approximates that of the blood, hence large quantities of base bound as bicarbonate can be eliminated in urine of moderate alkalinity. As much as 220 mM of bicarbonate can be excreted in a liter of urine of pH 8.0. In Figure 2, the concentration of bicarbonate in the urines from our 14 experiments are plotted against urine pH. The reaction of the most acid urine was pH 4.44, that of the most alkaline, pH 7.80. The maximum concentration of bicarbonate was 164 mM per liter, a figure which is relatively low because of the diuretic conditions in our experiments; the minimum concentration was 0.00001 mM per liter. The smooth curve of Figure 2 was calculated from the Henderson-Hasselbalch equation assuming a urine $p\text{CO}_2$ of 50 mm. Hg. It is evident that above

pH 6.5 the reaction of the urine is less alkaline than would be predicted from its content of bicarbonate. This deviation results from the fact, evident in Table I, that urines of high bicarbonate content have a higher $p\text{CO}_2$ than that assumed in calculating the curve. As shown in Figure 3, carbon dioxide tensions as high as 136 mm. Hg were observed in some urines of high bicarbonate content.

In Figure 3 the urinary partial pressure of carbon dioxide was plotted in two ways, on the left, against the simultaneously determined plasma partial pressure, and on the right, against the quantity of bicarbonate reabsorbed per 100 ml. of glomerular filtrate. It is evident from the lefthand graph that the $p\text{CO}_2$ of the urine is with few exceptions equal to or greater than that of the plasma from which it was formed. Those points below the dashed line of equivalence may be low because of inaccuracies introduced by loss of carbon dioxide or because of variations of pK' which would render the calculations inexact. The relationship, however, is less significant than that demonstrated in the righthand graph, which relates urinary $p\text{CO}_2$

and bicarbonate reabsorption. It is evident that at values of reabsorption less than 2.0 mM per 100 ml. of filtrate, $p\text{CO}_2$ was relatively constant, at values greater than this it increased rapidly. For reasons which will be amplified subsequently, it is believed that in the process of distal tubular reabsorption of bicarbonate, carbonic acid is liberated in the tubular urine. Were it possible to plot urine $p\text{CO}_2$ against distal rather than total bicarbonate reabsorption, a more exact correlation might be evident.

The relation between titratable acid and ammonia excretion and alkali reserve

Since the excretion of acid anions in combination with ammonia and as free titratable acid serves to replenish body stores of bicarbonate, the rates of both processes are determined in part by the extent of depletion of the alkali reserve (10). *Base economy*, which serves as a measure of the effective restoration of this reserve, is determined as the sum of the rates of ammonia and titratable acid excretion minus the rate of bicarbonate excretion (11). The contribution of each of these compo-

FIG. 4. THE RELATIONSHIP BETWEEN BASE CONSERVATION (AMMONIA AND TITRATABLE ACID EXCRETION), BASE EXCRETION (AS BICARBONATE), AND PLASMA LEVEL OF BICARBONATE

nents to base economy was studied at a series of plasma bicarbonate levels. The results of such an experiment are presented in Figure 4. Since the rate of excretion of buffer substances by the fasted subject in ammonium chloride acidosis is low, creatinine was infused to increase the elimination of titratable acid to levels sufficient for accurate evaluation. Throughout the experiment the rate of excretion of creatinine was maintained at a constant high value. In Figure 4 titratable acid and ammonia elimination are plotted upward, bicarbonate elimination downward, to emphasize their opposite relations to base economy. The titratable acid³ indicated was largely exogenous creatinine, to a slight extent endogenous phosphate as noted on the graph.

During the initial two control periods of this experiment, at plasma bicarbonate levels of 15 to 16 mM per liter, 0.150 mEq of titratable acid and 0.060 mEq of ammonia were excreted per minute. Base economy equalled the sum of these figures, for bicarbonate excretion was negligible. Sodium bicarbonate was then infused and the plasma concentration was raised as a linear function of time over a range of 16 to 30 mM per liter. Acid and ammonia excretion remained at their initial high levels until the fifth period, when at a plasma bicarbonate level of 20 mM per liter, the first perceptible reduction in these components of base economy was evident.

No significant excretion of bicarbonate occurred until the tenth period at a plasma concentration of 26.7 mM per liter, although before this level was reached, titratable acid and ammonia excretion had declined to a fraction of their control values. Thus over the range of 20 to 26 mM per liter the rates of excretion of acid and ammonia decreased in proportion to the increase in the rate of reabsorption of bicarbonate, in the absence of significant excretion of bicarbonate. We interpret this to mean that a type of competitive inhibition of acid and ammonia excretion results from increased reabsorption of bicarbonate. Since acid and ammonia are formed in the distal segment of the renal

tubules (12, 13) and since the final moiety of bicarbonate is reabsorbed from the tubular urine in this same segment (3), we incline to the view that interference occurs at this level. At plasma concentrations less than 20 mM per liter the quantity of bicarbonate delivered into the distal segment is so small that little interference results, and urine of maximal acidity and ammonia content may be formed. However, other factors, especially the duration of the acidosis, affect the excretion of ammonia. Perhaps these factors are the uncontrolled variables which render certain mathematical relationships between base conservation and alkali reserve (14) inexact in some instances.

DISCUSSION

The properties of the renal mechanisms for the reabsorption of bicarbonate in normal man are such as to assure stabilization of plasma concentration at a level of 24 to 28 mM per liter. At plasma concentrations less than 24 mM per liter, essentially all of the bicarbonate delivered into the renal tubules in the glomerular filtrate is conserved, none is lost in the urine. Furthermore acid elimination and ammonia excretion are stimulated as the plasma bicarbonate level falls below 24 mM per liter. Both processes serve to restore base to the body as bicarbonate and thus to rebuild depleted reserves. At plasma concentrations above 28 mM per liter a relatively constant quantity of bicarbonate, namely, 2.8 mM per 100 ml. of glomerular filtrate, is reabsorbed; the excess is excreted in the urine, and plasma concentration returns toward the normal value.

The nature of the tubular mechanisms accomplishing these ends cannot be completely defined at present but sufficient information exists to permit their partial characterization. It is evident that no less than two-thirds (15), and possibly as much as four-fifths or more (16) of the fluid filtered at the glomerulus is reabsorbed during its passage through the proximal segment of the renal tubule. According to Walker (15), the residual tubular fluid and hence the reabsorbate are essentially in osmotic equilibrium with the plasma. Only in the distal tubule does concentration or dilution of the tubular urine occur. Wesson (17) holds that electrolytes are actively reabsorbed in the proximal segment and that the removal of these and

³ Titratable acid values were calculated from the pH of the urine, collected in such fashion as to avoid loss of carbon dioxide, and the measured rates of excretion of creatinine and phosphate. They do not, therefore, include titratable acid contributed by dissolved carbon dioxide.

other osmotically active constituents from the tubular fluid creates a diffusion force which causes the return of water to the blood stream. Thus the composition of the residual tubular fluid varies in its course through the proximal segment owing to the progressive removal of its several valuable constituents and to the progressive concentration of its waste components, yet the osmotic pressure of this fluid remains nearly the same as that of the plasma, for the tubular epithelium is presumed to be freely permeable to water.

In the rat and guinea pig (15) and apparently in the dog as well (17), bicarbonate is reabsorbed relatively more rapidly than is water, chloride or sodium. Thus the concentration of bicarbonate in the proximal tubular fluid falls below, that of sodium remains nearly the same as, and that of chloride rises above its respective level in the glomerular filtrate. If the reabsorption of bicarbonate and chloride were the consequence of passive diffusion conditioned only by electrostatic forces and by the active transfer of sodium, one would expect chloride to be reabsorbed relatively more rapidly than bicarbonate, for the mobility of the hydrated chloride ion is greater than that of the hydrated bicarbonate ion.⁴ The preferential reabsorption of bicarbonate in the proximal tubule therefore suggests its active transport.

This active transport mechanism must be of such nature as to satisfy the following requirements. Ionic electroneutrality of the tubular fluid and reabsorbate must obviously be preserved. The capacity of the mechanism to transfer bicarbonate must be limited in some fashion, for as described above, all filtered bicarbonate in excess of 2.8 mM per 100 ml. is excreted. However, transport capacity, although limited, is not fixed, for at any given plasma level the quantity of bicarbonate reabsorbed is linearly related to glomerular filtration rate (3). These latter two characteristics in reality apply to the overall reabsorption of bicarbonate, but since the major reabsorption of this ion species occurs in the proximal segment, they must be considered to be characteristics of the proximal mechanism. Any further description of the nature of this mechanism is impossible at the present state of our knowledge.

⁴ This statement is based on the specific conductivities of the two ion species derived from the International Critical Tables.

From evidence presented previously (3) as well as that outlined above, the distal tubular mechanism for the reabsorption of bicarbonate would appear to be the same as that which converts urinary buffer salts into free titratable acid. This latter mechanism accomplishes the exchange of hydrogen ions, formed within the tubular cells, for fixed base bound by weak acid anions in the tubular urine. These acid anions are eliminated as titratable acid; the base is returned to the body as bicarbonate (18-20). A similar exchange of hydrogen ions for bicarbonate bound base would form carbonic acid in the tubular urine. Since carbonic anhydrase is absent from the tubular fluid, dehydration of carbonic acid to carbon dioxide would proceed slowly, and, providing any significant quantity of carbonic acid were formed, one would predict that the carbon dioxide tension of the bladder urine would exceed that of plasma.

As shown in the lefthand graph of Figure 3, the carbon dioxide tension of the urine equals or exceeds that of the plasma. As shown in the righthand one the greater the quantity of bicarbonate reabsorbed, the higher the carbon dioxide tension of the urine. We infer that at plasma concentrations less than 20 mM per liter, the bulk of the bicarbonate is reabsorbed in the proximal segment, little is delivered into the distal segment to be absorbed by ion exchange. Accordingly the carbon dioxide tension of the urine is low and approximates that of the plasma. At higher plasma concentrations, proximal reabsorption is incomplete, and appreciable quantities of bicarbonate are delivered into the distal segment to undergo reabsorption by ion exchange. As total absorption exceeds 2.2 mM per 100 ml. of filtrate, the distal contribution becomes appreciable, and the carbon dioxide tension of the urine rises rapidly to a value some three to four times that of the plasma.

The view of the identity of the distal ion exchange and bicarbonate absorption mechanisms is strengthened by the observation, illustrated in Figure 4, that there exists a type of competitive interference between bicarbonate reabsorption and titratable acid excretion, at least at plasma bicarbonate levels between 20 and 26 mM per liter. At plasma levels below 20 mM per liter no interference occurs for the bulk of the bicarbonate is absorbed in the proximal segment and little reaches the level of the distal ion exchange mechanism.

At plasma levels above 20 mM per liter bicarbonate reaches the distal segment in increasing quantities and bicarbonate bound base competes with base bound by fixed buffer acids in the exchange process. Accordingly, the excretion of titratable acid varies inversely with bicarbonate absorption over a range of plasma concentration of 20 and 26 mM per liter. Above 26 to 28 mM per liter frank excretion of bicarbonate occurs and titratable alkali is eliminated in the urine.

A third line of evidence favoring identity of the distal ion exchange and bicarbonate absorption mechanisms is derived from experiments on the dog described previously (3). Sulfanilamide blocks the excretion of titratable acid and reduces the reabsorption of bicarbonate. Presumably it inhibits the enzyme carbonic anhydrase which plays a role in the distal tubular exchange of hydrogen ions for base (18, 19). Bicarbonate reabsorption is only partially blocked by sulfanilamide; presumably it is the distal moiety, entering into the ion exchange mechanism, which is affected.

Although these experiments outline in a general way the relation between plasma concentration, reabsorption and excretion of bicarbonate, they throw no light on the means by which hyperventilation brings about increased bicarbonate excretion. Forced breathing, induced voluntarily or reflexly in consequence of anoxia, lowers the bicarbonate content of the blood, yet leads to the formation of alkaline urine (11). Obviously the capacity of the renal tubules to reabsorb bicarbonate must be reduced, but no evidence exists as to the nature or site of action of the stimulus which brings about this reduction. It is possible that changes in plasma pH may in some way yet to be defined exert a regulatory influence over bicarbonate reabsorption. It is well known that changes in plasma pH of considerable magnitude occur with hyperventilation.

SUMMARY

The renal reabsorption and excretion of bicarbonate have been studied in three normal subjects over a range of plasma concentration of 13 to 38 mM per liter. At plasma levels below 24 mM per liter essentially all of the bicarbonate entering the renal tubules in the glomerular filtrate is reabsorbed. Above 28 mM per liter a relatively con-

stant quantity, averaging 2.8 mM per 100 ml. of glomerular filtrate, is reabsorbed; the excess is eliminated in the urine. Under the conditions of our experiments the renal threshold is 25 to 27 mM of bicarbonate per liter of plasma. Evidence is presented that bicarbonate is reabsorbed by two dissimilar mechanisms, a proximal and a distal one. The latter mechanism appears to be the same as that which converts buffer salts of the tubular urine into free titratable acid. The properties of the proximal and distal tubular reabsorptive mechanisms of man are similar to those previously described in the dog.

THE BIOASSAY OF ADRENAL CORTICOIDS IN THE URINE OF PATIENTS WITH CONGESTIVE HEART FAILURE

By ALVIN E. PARRISH

(From the Department of Physiology, George Washington University School of Medicine, Washington, D. C.)

(Received for publication June 14, 1948)

Futcher and Schroeder (1) and Warren and Stead (2) suggested that changes in endocrine activity might be present in congestive heart failure and might explain some of the symptoms such as edema and sodium retention. Merrill, Morrison, and Brannon (3) found an increased concentration of renin in the renal venous blood. No other reports of endocrine changes in congestive heart failure appear in the literature. Since sodium and water retention are known to occur following administration of adrenal cortical hormones, especially desoxycorticosterone, studies were undertaken to determine if the urine of patients in congestive heart failure contained increased amounts of corticoid substances.

METHODS

Ten male patients with congestive heart failure were selected at random from the Gallinger Municipal Hospital. These represented four cases of hypertensive heart disease, one of rheumatic heart disease, four of arteriosclerotic heart disease, and one of chronic cor pulmonale associated with asthma. Their ages ranged from 28 to 70 years, and all but two were negroes. The study was restricted to males to eliminate any possible interference due to changes in the menstrual cycle. Six medical students, none of whom had any evidence of heart disease, were used as control subjects. Twenty-four hour samples of urine were collected without preservatives. In the case of the heart failure patients these were collected as soon after admission as possible, usually within the first 48 hours. The first stage of extraction was carried through in all instances within 12 hours after the collection was made.

Urinary corticoids were extracted by the method of Venning, Kazmin, and Bell (4); and the extracted material was stored in the refrigerator until used. Before use this material was taken up in 6 cc. of 10 per cent ethanol so that each cubic centimeter of the resulting solution represented a four-hour excretion of corticoids.

This material was assayed on young male rats of the Sprague-Dawley strain, using the survival time of adrenalectomized rats as one method of assay (5-7). The animals ranged in weight from 70 to 120 gm. Immediately after adrenalectomy these rats were placed on a diet of dog biscuit with 1 per cent sodium chloride and

5 per cent dextrose in their drinking water. After two to four days they were considered ready for use. At 9:00 a.m. of the initial day they were divided into cages of from five to ten rats and placed on a sodium-free diet (Table I) with distilled water for drinking. At 1:00 p.m. of this day they were given subcutaneously their first injection of 0.05 cc. of the alcoholic solution of corticoids. This was repeated at 12-hour intervals as long as the animals survived. With each assay at least one cage was given extract of normal urine and one cage was given 10 per cent ethanol, using the same size dose. Each cage of animals was checked every eight hours for deaths and the survival time recorded in hours.

TABLE I
Sodium-free diet (29)

Casein (vitamin free)	450 gm.

‡ 2 mg. per cc. of calciferol.

§ 50 mg. per cc.

Glycogenic activity was assayed by using male rats weighing 140 to 180 gm. (8). These were adrenalectomized and placed on a diet of dog biscuits and a solution of 1 per cent NaCl. Three days following adrenalectomy these rats were taken off food for 24 hours. Starting at 6:00 a.m. on the day following this fast they were each given 0.20 cc. of the pooled urinary extracts (as described in the results) every hour for seven consecutive hours. One to two hours after the last injection they were given 0.2 gm. of sodium evipal intraperitoneally, and approximately 1 gm. of liver was removed and plunged into hot 30 per cent KOH. Using the method of Good, Kramer, and Somogyi (9) the liver glycogen was isolated and hydrolyzed and the resulting glucose determined by the Shaffer-Somogyi method

(10). The results were then expressed as mg. of glucose per 100 gm. of body weight.

The statistical significance of the data was determined by obtaining the value of "P" corresponding to the calculated value of "t" for the difference between the means of the results obtained in the experimental and the control animals (11).

RESULTS

The effect of urine extracts on the survival time of adrenalectomized rats on a sodium-free diet is summarized in Table II. Four urine extracts of patients with congestive heart failure produced a significant prolongation of the survival time of adrenalectomized rats over that of normal subjects when these were assayed simultaneously. The remaining six did not. Correlating this with the clinical findings, it can be seen that these former four patients were sicker than the remainder with one exception, E. J. Three of the four had orthopnea, all had three to four plus peripheral edema, and three to four plus pulmonary edema. Clinically, E. J. would also fall into this group; but his urine did not prolong the lives of the experimental animals significantly. Of the former group, three had arteriosclerotic heart disease and one had chronic cor pulmonale. In the latter group there were four cases of hypertensive heart disease, one of arteriosclerotic heart disease, and one of rheumatic heart disease.

In order to show that adrenalectomized animals would live under the conditions of the experiment if given one of the cortical hormones, 12 adrenalectomized rats were given subcutaneously 0.5 mg. of desoxycorticosterone acetate in propylene glycol twice daily. The procedures used were the same as those used in animals receiving injections of urine extracts. There were no deaths during the desoxycorticosterone injections which were continued for 216 hours. After these injections were stopped the animals lived an average of 194 ± 109.1 hours. The long survival time of these rats subsequent to discontinuing the desoxycorticosterone was possibly due to the slow absorption of the hormone in some animals.

In order to show that the lives of adrenalectomized animals would not be prolonged by the solvent (10 per cent alcohol) alone, 25 animals were given 10 per cent alcohol using the same size dose and procedures as with those animals receiving urine extracts. These animals lived an aver-

age of 108 ± 38.0 hours. This value is approximately the same as the average for the survival time of animals receiving normal urine extracts (95.3 ± 44.3 hours).

In practically all animals receiving the urinary extracts there were observed toxic reactions. Animals became sluggish within two to four days after beginning the injections. Rats weighing less than 70 gm. were not used since it was found that they died very early in a trial run (50.5 hours). Room temperature could not be controlled satisfactorily, and some animals died on cold nights. These factors are probably responsible for the large standard deviations in some instances.

Based on the clinical and experimental findings, the urine extracts were pooled into two groups. Group A consisted of those patients who were the sickest and whose extracts resulted in a significant

TABLE III

Comparison of glycogenic activity of urine extracts from normal subjects and from heart failure patients

Extract	Average liver glycogen (mg./100 gm. of rat)	"P"

increase in survival time in adrenalectomized rats (urine extracts of patients C. C., C. D., R. L., and C. Corn.). E. J. was also placed in this group because clinically he belonged there and it was felt the survival time produced by his extracts was similar to that of this group although it was not statistically significant. Group B consisted of those patients who were not so sick and whose extracts resulted in no increase in survival time (urine extracts of patients W. N., I. D., H. D., T. B., and F. S.). These two pooled groups were used in the assay of the glycogenic activity of the urine extracts. The results are given in Table III. Both groups show a marked increase of glycogenic activity over that of control urine extract. The slight difference between the two experimental values was not evaluated because of the small number of animals used.

DISCUSSION

The results of this study indicate that there is an increase in the urinary excretion of corticoids in patients with congestive heart failure. Of the ten patients studied, four who appeared clinically to be the sickest, excreted substances which prolonged the life of adrenalectomized rats while the remaining six did not. There was one patient who clinically belongs in this group whose urine extracts did not prolong the life of adrenalectomized rats. Both of these groups of patients, however, excreted an increased quantity of glycogenic corticoids. An increase of corticoid substances in the urine has been considered as an indication of increased adrenal cortical activity (4-7). There is, however, in these patients another factor which must be considered. All but two of the patients had liver enlargement; and since the liver plays an important role in the inactivation of steroid hormones (12), the question arises that in these cases there might have been enough liver damage to cause only an apparent increase in corticoid secretion rather than a true increase in corticoid production. Some authors (13) report liver dysfunction in a large percentage of patients with heart failure, but this cannot be correlated with the degree of failure (14).

Increased adrenal cortical activity in other instances is believed to be the result of a reaction to various "non-specific stimuli" (15). Of these anoxia has been shown to produce increased adrenal cortical activity (15-18) and Langley and Clarke (16) believe that disturbances in acid-base balance resulting from hyperventilation can stimulate the adrenal cortex. Both anoxia and hyperventilation are present in patients with heart failure and the increase in corticoids found in this study possibly represents adaptation to these non-specific stimuli.

With an increase in adrenal cortical activity sodium retention would be expected, since some of the cortical hormones, especially desoxycorticosterone, act on the renal tubules to promote the reabsorption of sodium from the glomerular filtrate (19, 20).

Other investigations (21-23) indicate that the primary cause of sodium retention in heart failure is a decrease in renal blood flow and glomerular filtration which results from a shunting of blood

away from the glomeruli secondary to renal vascular changes. Merrill (21) and Mokotoff, Ross, and Leiter (22) have concluded that there is no increase in the reabsorption of sodium in heart failure but that its reabsorption is proportional to the glomerular filtration rate. This suggests either that the adrenal corticoid production is not increased sufficiently to affect sodium reabsorption in heart failure or that the adrenal corticoids act on the renal vascular system. Experimental evidence to support the latter is inconclusive. Talbott, Pecora, Melville, and Consolazio (24) studied renal function in patients with Addison's disease and believe that the decreased renal function observed was due to a decreased tone of the efferent arterioles of the kidney and that this was corrected following the administration of desoxycorticosterone. No changes in renal function were observed in normal individuals following the administration of desoxycorticosterone acetate. Waterhouse and Keutmann (25) believe that in Addison's disease desoxycorticosterone produces a vasoconstrictor effect on the vascular system of the kidney. Other investigators have produced changes in the kidney with desoxycorticosterone (15, 20, 26, 27). Swingle (28) believes that desoxycorticosterone may affect the tone of arterioles. At the present time it seems more likely that the increase in corticoid excretion represents a result rather than a cause of the symptoms seen in heart failure. However, because of the close relation between clinical symptoms and the increase in corticoid excretion, further investigation is to be undertaken.

SUMMARY

1. The urine of ten patients in congestive heart failure was studied for the presence of adrenal corticoids and compared with normal control urine.
2. Of these ten patients, four showed an increase of corticoids over that found in normal urine which prolonged the life of adrenalectomized rats.
3. An increase in corticoids with glycogenic activity was observed in urine obtained from heart failure patients over that of urine obtained from normal control subjects.
4. The possible place of increased adrenal cortical activity in heart failure is discussed.

ACKNOWLEDGMENT

The author wishes to express his appreciation to Dr. Errett C. Albritton, Dr. Abraham Dury, and Dr. Chester E. Leese of the Department of Physiology, George Washington University, for their encouragement and criticism of this work.

AUTOANTIBODIES IN HUMAN GLOMERULONEPHRITIS¹

By KURT LANGE, MICHAEL M. A. GOLD, DAVID WEINER, AND VERA SIMON

(From the Department of Medicine, New York Medical College, Flower and Fifth Avenue Hospitals, and the New York Medical College Research Unit [Metropolitan Hospital], New York City)

(Received for publication June 28, 1948)

It has often been suggested that the picture and course of human glomerulonephritis could be best explained by an antigen-antibody reaction. There are many clinical facts which support such a hypothesis. The interval of 10 to 20 days between the primary streptococcal infection and the first appearance of clinical signs of acute glomerulonephritis, the persistent absence of direct evidence of streptococcal invasion of the kidney itself with evidence of severe general involvement of the glomerular apparatus and the often irreversible progress of the disease seem strongly to suggest such a possibility. In our studies on the nephrotic syndrome (1) during the last few years using the fluorescein and other methods for determining capillary permeability, we had the impression that during this stage of chronic glomerulonephritis we are dealing with a diffuse damage of the entire capillary network throughout the body, possibly produced by an "allergic" reaction.

Good evidence has been presented that by an antigen-antibody reaction a picture very similar to human glomerulonephritis and its different stages can be produced in experimental animals. Masugi (2) has shown that a chronic glomerulonephritis can be produced by the injection of a heterologous immune antikidney serum. Sarre and Wirtz (3) were able to demonstrate that such antibodies are rapidly and selectively adsorbed by the kidney and thus disappear out of the circulation, giving rise to specific changes in the kidney. They were also able to show that other organs bind these specific antibodies to a much lesser extent. Swift and Smadel (4) demonstrated the specificity of such antikidney serum by the fact that an injection of kidney extract immediately preceding the injection of the antikidney serum prevented kidney damage. Injection of liver extract did not afford this protection. Burky (5) in turn showed that

lens material of rabbits when incubated with staphylococcus toxin and injected into rabbits produced antibodies to lens which in turn attacked the lens of the same animal species. Hecht, Sulzberger and Weil (6), by the utilization of the synergistic action of staphylococcus toxin and of homologous skin antigen, succeeded in the production of specific antiskin antibodies.

Cavelti (7-9) was able to produce, in a high percentage of rabbits and rats, a picture similar to human glomerulonephritis and rheumatic heart lesions by the injection of homologous kidney and heart extracts, respectively, incubated with streptococci or staphylococci. He also succeeded in showing the appearance of specific antibodies in the blood of such animals with the modified colloid technique of Cannon and Marshall (10). Schwentker and Comptoier (11) also demonstrated that in rabbits antibodies to kidney can be produced by injecting a rabbit kidney extract previously incubated with staphylococcus or streptococcus extract. They also showed that in the majority of recent cases of scarlet fever antibodies to kidney can be found by complement fixation one to two weeks after the acute phase but that similar antibodies can be demonstrated only in a small percentage of normal individuals.

Stimulated by these experiments and search for a possible "allergic" mechanism which would explain the increased capillary permeability in acute nephritis and the nephrotic stage we investigated the bloods of 23 patients with different stages of glomerulonephritis and of 68 controls in whom there were no signs of glomerulonephritis by history or clinical examination. Since we deviated in some major points from the colloid method as suggested by Cannon and Marshall (10) and by Cavelti (12) a full description of the method used is essential to enable reproducibility and to avoid if possible pitfalls in the extremely delicate and somewhat unpredictable method.

METHOD

I. Preparation of collodion particles

All water used in the preparation of collodion particles is triply distilled in glass and all apparatus used is completely made of glass. One-half pound of collodion (non-flexible Merek or Mallinckrodt) is very slowly poured into 2 liters of water with constant stirring. The mass so formed is then washed with four changes of just enough water to cover it. The mass is then dried after excess water has been pressed out with clean hands. The mass is now left to dry for three days in a beaker at room temperature. Thereafter a 5% stock solution is prepared by adding acetone to the mass in a water bath at 40° under constant stirring. This stock solution may be used for three months if kept in a dark bottle.

For a test of 400 tubes 75 cc. of stock solution are needed to obtain the necessary particles. A motor-driven stirring rod is suspended close to the bottom of a beaker containing the stock solution. This is done in a water bath at 40° C. While stirring, a mixture of three parts water to one part acetone is added in a fine stream until a gelatinous mass separates and the supernatant fluid becomes cloudy. This supernate is then discarded and the mass redissolved in a somewhat smaller volume of acetone. This procedure is repeated twice, each time discarding the supernate. The fourth and succeeding supernates are collected in a flask containing 300 cc. cold water. This procedure is repeated until the gelatinous mass fails to form. Compressed air is then bubbled through the suspension until all acetone has evaporated. This requires two days. The suspension is then filtered through glass wool. Subsequently, the suspension is washed by the following procedure: 1) In an angle centrifuge the suspension is spun at 3000 r.p.m. for five minutes. The largest particles settle down and are discarded. 2) The supernate is recentrifuged at 2500 r.p.m. for one hour. The supernate is now discarded and the precipitate resuspended by gentle agitation in 50 to 100 cc. of water to give a milky suspension. 3) Again this suspension is centrifuged at 2500 r.p.m. for one hour. The supernate is discarded and the precipitate resuspended and centrifuged as before. 4) At the end of this third one-hour period the particles are resuspended in the smallest volume of water that will permit complete resuspension and centrifuged at 3000 r.p.m. for five minutes discarding the precipitate. The supernate is used as stock suspension and should not be kept for more than a week. It is recommended that the collodion suspension be examined under the Fisher-Kahn viewer before use for the absence of self-agglutination. If clumps are visible the suspension must be discarded.

II. Preparation of the antigen

The kidneys obtained from autopsies performed within a few hours after death are cut up, washed in several changes of saline until free of blood and ground in a Waring Blendor. Enough 1.1% saline solution made with triple distilled water is added during the grinding

to make a 20% emulsion. Care should be taken that the solution does not overheat during the grinding process. The suspension is then centrifuged at high speed until the supernate is absolutely clear. This takes between two and three hours at 3000 r.p.m. If the solution does not clear at this speed further centrifugation at 5000 r.p.m. should be used. The clear supernate is stored at approximately -20° C. The effectiveness of antigens seems to decrease after 10 days. The antigens differ widely in antigenic properties, a question which requires further study.

III. Coating of collodion particles

After studying many methods of coating the following was found most satisfactory. The final collodion suspension described above is tested for the dilution which is necessary to make it match tube No. 3 of McFarland's scale (13). Small amounts of undiluted collodion suspension and undiluted antigen solution are then mixed in such a way that when the proper amount of 1.1% saline is added to make the collodion suspension match McFarland's tube No. 3 the antigen is in a dilution of 1:60. Various antigen titrations with different antigens and different test sera indicated that an antigen dilution of 1:60 is the most effective dilution although variations with different antigens are considerable. The final mixture of collodion and antigen is permitted to stand at room temperature for one hour before use.

The sera

Bloods to be tested should be collected on the day before use with dry syringes, allowed to clot firmly and the sera taken off. They are kept overnight in an ordinary refrigerator. Prolonged storage of sera shows increasing non-specificity in tests. The last 46 tests were run with the sera inactivated for one hour at 56° C. It is the authors' impression that this procedure eliminates non-specificity but also depresses somewhat the specific titres obtained. It has been accepted at present as part of the routine procedure.

The test

Serial dilutions of the sera by the doubling method and employing 1.1% saline are set up in serological test tubes so that each tube contains 0.5 ml. of the diluted serum. The first tube contains a dilution of 1:5. Then 0.2 ml. collodion-antigen mixture is added to each tube. Controls are made up of each serum (1:5 to 1:40) with 0.2 ml. uncoated collodion in such a dilution as to match McFarland's tube No. 3. Additional controls are made of 0.5 ml. saline and 0.2 ml. of coated collodion particles but no serum. The tubes are stoppered and allowed to stand at room temperature for one hour. Thereafter they are spun in an angle centrifuge for three minutes at 1400 r.p.m. Each rack of tubes is then inverted sharply three times to resuspend the particles and the tubes are then read in a Fisher-Kahn viewer. The positive tubes will show discrete small particles with a clear

surrounding fluid, while the negative tubes show a milky suspension. Numerous modifications of this last method were tested but the method as described above was found to be the most reliable. The use of kidneys of young rabbits as antigens was studied but the tests were too few to be conclusive.

The method is very delicate and cumbersome. Occasionally, entire runs will be negative or positive, without any known deviation in technique. Such runs have to be excluded.

The particular antigen used in our tests seems to be of great importance. It was found that adult human kidneys are much less satisfactory than kidneys of infants or stillbirths. This fact has been demonstrated by us repeatedly and seems rather important not only for the performance of the test but also for the general aspect of the physiologic mechanism. But even kidneys from young individuals vary considerably in antigenic quality for unknown reasons. Fractionation and concentration of the antigen may eventually aid in the explanation of this observation. In order to secure a uniform statistical basis each test was run in such a way that approximately the same number of control and nephritic bloods were used in each run. In 11 tests the sera were absorbed with human liver extracts. The results did not differ from those obtained without absorption. To exclude the possibility of blood group factors influencing the results 11 tests were carried out with absorption of the sera with mixed red cells. Again the results obtained with or without absorption did not deviate, indicating that these factors do not influence the specificity of the results obtained.

RESULTS

Twenty-three cases of glomerulonephritis were examined in 122 individual determinations. The cases were arbitrarily classified as early or late nephritis on the basis of duration of signs or symptoms, a duration of less than one year being considered early and longer than one year being considered late. The 12 cases of early nephritis included four cases of acute glomerulonephritis, four which started with a nephrotic syndrome and four cases of chronic glomerulonephritis of less than

one year's duration. The 11 cases of late nephritis were all chronic glomerulonephritis ranging in duration from one and one-half to 12 years. Six of the late cases had marked reduction of renal function with inulin clearances of less than 18 ml. per minute and chemical retention. In all, 44 determinations were done in the early and 78 in the late cases. The results are given in Table I.

The group of nephritics showed titres of 1:10 or above in 75% of the determinations. The average titre in this group of positive reactions was 1:623. Of the determinations in nephritics, 18% showed a titre of 0, and 7% a titre between 0 and 1:10. The highest titres obtained in this group (1:80,000) were obtained on two occasions from different specimens. Since these values were exceptionally high they were not used as such in the statistics but reduced arbitrarily to the next high value of 1:5000 in order not to raise the average titre disproportionately. Of 23 cases in all stages of nephritis 18, or 78.3% were positive more than 60% of the times tested.

Splitting the group of nephritics up between early and late nephritics the following results were obtained. Of the 12 cases considered as early nephritis with 44 determinations 30, or 68% showed titres of or above 1:10. The average titre was 1:918. A titre of 0 was obtained in 11, or 25% of the determinations; 7% had titres between 0 and 1:10. The 11 cases of late nephritis with 78 determinations showed a titre of 1:10 or above in 61 tests, or 78% of the determinations. The average titre was 1:337. A titre of 0 was present in 11, or 14% of the determinations and a titre below 1:10 but above 0 in seven tests, or 9%.

Of all nephritics examined there was not a single case where on repeated determinations the titre

over 50			2

tests, or 19.0% of the control determinations were 1:10 or above. The average titre in this positive group was 1:78. Seventy-six determinations, or 60% of the control tests showed a titre of 0, while 26, or 21.0% showed titres above 0 but below 1:10. Of the 68 control cases four, or 6% were positive more than 50% of the times tested. On each one of these four only one determination was done. It should be stated that of the 68 control cases 26 were tested more than once. In these, 84 determinations were done, of which 20, or 23.8% were positive (1:10 or above). None of these 26 cases were positive in more than 50% of the tests (Table I).

DISCUSSION

From the data described it will appear that in a high percentage of nephritics of all stages of the disease the occurrence of antibodies to normal kidney can be demonstrated. The results described may still be improved in the future since many of the tests were technically imperfect in the beginning and the antigen certainly requires much fur-

ther study with the view of purification. If, in the majority of cases of chronic glomerulonephritis, antibodies to normal kidney tissue are constantly or commonly circulating in the blood the progressive course of the disease would be well explained. Whether the wide variations in titre in an individual case and the occasional complete absence of a positive titre are due to technical imperfections of the delicate method or whether they really represent variations in antibody formation remains to be seen. One case with the nephrotic stage of chronic glomerulonephritis showed a titre of zero during an attack of measles. Subsequently, the nephrotic phase disappeared as is often observed. Two weeks after the measles the titre went up to 1:40. If it is true that as a result of measles the antibody level in general is severely depressed it would possibly explain the temporary clearing of certain phases of chronic glomerulonephritis subsequent to rubella. The fact that none of the cases of glomerulonephritis showed a consistently negative titre seem to confirm the impression that the mechanism of the disease is related to an antigen-antibody reaction. The presence of high antistreptolysin titres and their increase subsequent to reinfections seem to indicate that the streptolysins may possibly be the factor which split up certain otherwise nonantigenic kidney proteins and combine in a hapten linkage so that they become antigenic. The antibodies in turn are then no longer restricted to the hapten-kidney linkage but attack kidney substance directly in the form of a direct precipitin reaction, as demonstrated *in vitro* by the precipitin reaction with the kidney antigen made visible by the collodion agglutination technique. The high specificity obtained by using infants' kidneys and the marked nonspecificity obtained from adult material may explain the high incidence of glomerulonephritis in young individuals. Further studies to correlate antistreptolysin titres with autoantibodies to kidney are in progress. Rantz and his collaborators (14) have shown that during the first two years of life antistreptolysin titres are very low. This may explain the relatively low incidence of glomerulonephritis in infancy in spite of the high antigenicity of infant kidney tissue. Cavelti's original report that a high percentage of cases of rheumatic fever show antibodies to heart in their sera has recently been modified (15) since tests with a modified antigen

did not show the same degree of specificity. Here again the decisive role of the antigen has been demonstrated, and it is possible that infant's heart may yield better and more consistent results. The low incidence of positive titres in normal controls makes the results more significant.

At present the technical difficulties of the method described in this paper and its occasional complete failure do not make it applicable as a routine clinical test. It is to be hoped that with further knowledge of the antigen new and simpler methods can be worked out for more general use. Our attempts with the complement-fixation method as suggested by Schwentker have failed. The methods as suggested by Hecht, Sulzberger and Weil (6) should be investigated.

One cannot avoid speculating on the possibility of neutralizing these antikidney antibodies as a therapeutic approach if they should prove to be a link in the pathogenesis of glomerulonephritis.

The fact that all authors were forced to employ many injections of their "nephrotoxins" to produce persisting lesions suggests that human nephritis does not develop and progress from a single insult but rather from the constant presence and occasional stimulation of antibodies to renal tissue. This lends support to the thought that a maintained neutralization of the antibodies may arrest or interfere with the progress of the disease.

SUMMARY

1. The clinical and experimental evidence supporting the concept that glomerulonephritis is due to a continuous organ-specific antigen-antibody reaction is reviewed.

2. A modified collodion particle technique for detecting antibodies to kidney tissue is described.

3. In 23 cases of glomerulonephritis of all stages antibodies to human renal tissue were demonstrated in 75% of the 122 tests done (average titre 1:623) and 18, or 78.3% of the cases were positive in more than 60% of the tests.

4. In 12 cases considered as early nephritis 68% of the 44 determinations done were positive (average titre 1:918).

5. In 11 cases considered as late nephritis 78% of the 78 determinations done were positive (average titre 1:337).

6. In 68 control subjects antibodies to human renal tissue were demonstrated in 19% of the 126 determinations (average titre 1:78). Four, or 6% of the 68 cases were positive in more than 50% of the tests.

7. Renal antigens obtained from infants or stillbirths show a greater specificity and higher titres than antigens from adult renal tissue.

8. The importance of the continuous presence of antibodies to kidney in a high percentage of cases of nephritis is discussed in relation to the clinical course of the disease and a possible therapeutic approach is suggested.

We are indebted to Dr. Marion B. Sulzberger for many helpful suggestions; to Dr. Harriet Chase for her help in working out the methods; and to Drs. L. Slobody, M. Nareff and J. F. Kilgus for clinical material.

THE HYALURONIC ACID OF SYNOVIAL FLUID IN RHEUMATOID ARTHRITIS

By CHARLES RAGAN AND KARL MEYER

(From the Departments of Ophthalmology and Medicine, Columbia University College of Physicians and Surgeons, and the Edward Daniels Faulkner Arthritis Clinic of the Presbyterian Hospital, New York City)

(Received for publication July 3, 1948)

Rheumatoid arthritis is considered a disease which involves the connective tissue and supporting structures of the body with its primary nidus in the interfibrillar ground substance of these structures (1). The ground substances are thought to be composed of mucopolysaccharide-protein complexes. The nature of two of the polysaccharides is known—chondroitin sulfuric acid and hyaluronic acid. The latter has been isolated from skin, the vitreous of the eye and from synovial fluid (2). The synovial space has been regarded as an enlarged tissue space (3) and synovial fluid may be obtained with relative ease in many patients with rheumatoid arthritis. A study of the hyaluronic acid in the synovial fluid of patients with rheumatoid arthritis in contrast to normals seemed worthwhile as the characteristics of the hyaluronic acid thus obtained might parallel changes in other mucopolysaccharides in the smaller connective tissue spaces throughout the body.

Hyaluronic acid in synovial fluid is the component of the fluid which is responsible for its high viscosity (4). A variety of quantitative viscosimetric methods have been applied to the viscous nature of synovial fluid since 1925 (5). These have yielded conflicting data but most seem to agree that normal joint fluid is a very viscous material (6). Bauer, Ropes and Waine (3) demonstrated that there is a wide range of viscosity values obtained from both normal and pathological fluids. We have shown that the viscosity of normal human knee joint fluid varies inversely with the degree of peripheral edema present (7). When joint fluid or purified hyaluronic acid is diluted with 0.85 per cent saline or distilled water an exponential curve is obtained (8, 9), and with fluids of high viscosity small increments of diluent fluid cause marked decreases in viscosity. For these reasons, viscosity alone cannot be taken as an index of the concentration of hyaluronic acid or of the extent of polymerization of the mucopoly-

saccharide. The concentration of hyaluronic acid may be approximated by the mucin clot method of Bauer *et al.* (3), but the clot thus formed contains both protein and hyaluronic acid and changes in protein concentration could cause errors in the determination of hyaluronic acid concentration. Recently a method has been described whereby the hyaluronic acid content of 1 cc. of fluid can be determined with an accuracy sufficient for a biological method (2).

MATERIALS AND METHODS

Joint fluid was drawn at autopsy from the knees of 11 patients without joint disease. In some of these insufficient fluid was obtained for a 5-cc. viscosimeter. These fluids were diluted with 0.85 per cent saline and the viscosity and turbidimetric determinations of hyaluronic acid were made on the same diluted sample. Fluid was obtained from one or both knee joints of 35 patients with rheumatoid arthritis. Viscosity was determined as described previously (7). Hyaluronic acid concentration was determined by the method of Meyer (2).

The exponential curve derived from dilution of synovial fluid or pure sodium hyaluronate becomes a straight line when the logarithm of the viscosity is plotted against dilution (Figure 1). Dilution mirrors the concentration of hyaluronic acid and thus a straight line relationship exists between the log viscosity and concentration. A quotient obtained by dividing the log viscosity by the concentration would be constant for a given fluid regardless of the amount of diluent extracellular fluid introduced. Since the increased viscosity of synovial fluid is due almost completely to the hyaluronic acid present (7, 10) and the viscosity is an index of the polymerization at a given concentration, this quotient gives an approximation of the mean polymerization of the hyaluronic acid present in a sample of fluid. A highly viscous fluid with a low concentration would yield a high quotient and would indicate an highly polymerized hyaluronate. Thus the extent of polymerization would vary directly with the quotient.

RESULTS

In the normal fluids examined, Table I, the quotient was greater than ten in all. Normally

FIG. 1. DILUTION CURVES PLOTTED AGAINST RELATIVE VISCOSITY $\times H_2O$ AND LOG RELATIVE VISCOSITY $\times H_2O$

(1) Knee joint fluid obtained at autopsy from a patient without joint disease. (2) Knee joint fluid from a patient with rheumatoid arthritis. (3) 0.5 per cent Na hyaluronate.

polymerized hyaluronate would have a quotient of ten or above. In the fluid from patients with rheumatoid arthritis (Table II), the quotient was with few exceptions less than ten, which would imply that the hyaluronate in these fluids was less highly polymerized. The severity or intensity of the disease seems to bear some relation to the extent of polymerization of the hyaluronate. With

one exception, patient A. Da., all patients in the group with a quotient above 8.10 exhibited few of the criteria of a generalized illness. With the exception of A. Da., these patients could be grouped as smouldering cases or cases in remission. The four patients with quotients above ten were all what is commonly known as "burned-out cases" of long duration with resultant deformity and few

BLOOD OXYGEN STUDIES IN PATIENTS WITH POLYCYTHEMIA AND IN NORMAL SUBJECTS¹

By L. R. WASSERMAN,² R. L. DOBSON, AND J. H. LAWRENCE

(From the Division of Medical Physics and Division of Medicine,
University of California, Berkeley³)

(Received for publication December 22, 1947)

During the past few years various studies have been undertaken in this laboratory in an attempt to elucidate the pathological physiology and nature of polycythemia vera. Although the etiology remains obscure, interesting data have been accumulated on (1) blood oxygen saturation, (2) O₂ consumption and CO₂ production, (3) diffusion of gases across the alveolus-blood barrier, and (4) bone marrow findings. The present paper is concerned with a brief discussion of blood oxygen saturation in polycythemia and the results of determinations made on 74 subjects, 48 of whom were suffering from polycythemia vera. Subsequent reports will cover the remaining phases of the investigations and others.

METHODS

The diagnosis of polycythemia vera was made by the usual clinical and hematologic methods which included a complete blood count, packed cell volume, and sternal marrow aspiration. Blood volumes were done on some patients employing the dye T-1824, radioactive colloids of zirconium and yttrium (1), the CO method, or by the use of radioactively labeled red cells. Viscosity determinations and circulation times were also done in most cases. All patients had chest X-rays to exclude pulmonary pathology, and no patient with a chronic cardiac or pulmonary history was included in this series except as noted in the cases of secondary polycythemia.

Blood was drawn from the resting patient anaerobically from either the radial or brachial artery, and the oxygen content and capacity determined by the micro gasometric technique of Roughton and Scholander (2). Arterial capillary blood from the lobe of the ear drawn anaerobically into a tuberculin syringe by means of a small glass ear cup was found to give the same results, and after sufficient controls had been done the ear method

was used exclusively. In this method the whole ear is warmed for one-half hour by placing over it an anesthesia mask containing a small electric bulb. After warming, a small incision with a No. 11 surgical blade will produce a free flow of arterial capillary blood which can be rapidly withdrawn into the syringe containing a drop of mercury and previously rinsed with either heparin or a heparin-fluoride mixture. After the blood is collected, the ear cup is removed from the short rubber tubing connecting it to the syringe, and the tubing is turned on itself and made airtight with a rubber band. The drop of mercury is then used to mix the blood and anticoagulant by rapidly turning the syringe from side to side. The analysis must be made within a few hours, and the syringe with blood must be kept on ice at all times except when the actual determinations are being made.

RESULTS

For purposes of comparison the cases of polycythemia vera were divided into two groups, those with hematocrits below 50% and those above. A total of 48 cases of polycythemia vera was examined on whom 97 oxygen saturation determinations were done, 70 by ear capillary method and 27 by the usual radial or brachial artery method (Tables I and II). Analyses of the oxygen saturation were also done in 18 normal persons (Table III), in five patients with hypochromic anemia (Table IV) and in three cases of erythrocytosis secondary to chronic pulmonary or cardiac disease (Table V).

Eight cases of polycythemia vera had packed red cell volumes below 50%. These patients had been treated with either phlebotomies or radioactive phosphorus before the oxygen determinations were done. The average hematocrit was 44.5 ± 0.62 and ranged from 41.5 to 46.8. The blood oxygen saturation determined on ear capillary blood ranged from 90.0 to 98.4% with an average of $93.9 \pm 1.1\%$. In four of these cases arterial blood from the brachial artery gave a slightly lower oxygen saturation, the results ranging from 88.2 to 93.8% with an average of $91.3 \pm .3\%$.

Average			63.2					94.7				94.5	

The remaining 40 cases of erythremia had an average hematocrit of $63.2 \pm 1.8\%$ with a mean oxygen saturation of $94.7 \pm 0.36\%$ as determined on ear capillary blood. In 13 of these cases with an average packed cell volume of $67.3 \pm 3.9\%$, the large artery blood oxygen saturation was $94.5 \pm 1.3\%$.

Normal and hypochromic anemia cases examined in the same manner yielded similar results, viz., $95.1 \pm 0.59\%$ and $96.0 \pm 1.1\%$, respectively.

The three cases of secondary polycythemia yielded low oxygen saturation, the results ranging from 75 to 88% with a mean of $79.0 \pm 4.5\%$.

DISCUSSION

Few complete studies of arterial oxygen saturation in polycythemia vera are available. There is general agreement, however, among the scattered reports that saturation is within normal limits. In a total of 14 reported determinations in uncomplicated polycythemia vera results ranged from 91.0% to 97.0% (3-7), the average of 93.6% being slightly lower than an average of 95.5% reported

for a series of 15 normal individuals (8). These figures compare favorably with those obtained in our study.

Bauer, Lawrowsky, and Skujin suggest after studying a large series of patients, two of whom had polycythemia vera, that there is a lessened degree of oxygen saturation of the hemoglobin as the amount of hemoglobin increases, so that the amount of oxygen carried by a given amount of

hemoglobin would be greater in a normal than in a patient with polycythemia (9). In the series of cases studied by us, patients with hematoerits as high as 81% had normal oxygen saturation. Increased oxygen capacity with normal oxygen saturation was reported by Altschule and his co-workers although no figures were shown (10). Moschowitz has used arterial oxygen saturation as the important diagnostic criterion in differentiating between uncomplicated polycythemia vera and secondary erythrocytosis due to hypertension of the pulmonary circulation or prolonged mountain sickness, saturation being normal in true polycythemia (11). Hitzengerger in reporting normal arterial oxygen saturation in six patients with polycythemia vera also stresses this point (6).

It has been suggested by Bansi and Groscurth that the hemoglobin in polycythemia vera does not give up its oxygen to the tissues as readily as does normal blood (12). Isaacs, however, has shown that in polycythemia vera the hemoglobin is normal in all respects, and the oxygen unsaturation of venous blood is within normal limits (13). He found the venous unsaturation to be about 5 vol.%,

the same as the average found by Harrop in 15 normal cases (8). Altschule and his coworkers reported similar results (10).

Fitz interpreted normal arterial oxygen saturation in erythremia as due to increased pulmonary ventilation (14). Harrop and Heath studied alveolar gas diffusion in seven cases by determining the diffusion constant for carbon monoxide, and while finding the blood oxygen content to be high and the saturation low but within normal limits, reported a decrease in the pulmonary permeability to oxygen (3). They measured blood oxygen saturation in three of the patients immediately after exercise, and found significantly lower figures than they had obtained at rest. The failure to maintain normal saturation during a time of increased metabolic demand for oxygen, they felt, was linked to poor pulmonary permeability.

Oxygen saturation of hemoglobin is a function of the partial pressure of oxygen dissolved in the blood. This pressure of oxygen is dependent on the diffusion of oxygen across the alveolus-blood barrier and is in equilibrium with the alveolar oxygen tension of about 100 mm. Hg. Normal oxygen saturation in polycythemia vera would thus seem to signify a normal pressure of oxygen and would further seem to indicate normal diffusion across the alveolar membrane. This is supported by additional experimental evidence to be reported.

It will be noted that the figures for oxygen saturation we report as normal are lower by a small percent than those of some other recent authors. Comroe, for example, in arterial oxygen tension studies reports an average pressure of oxygen of 93 mm. Hg corresponding to about 98% oxygen saturation (15). Direct spectrophotometric studies of the circulating blood of normal dogs by Drabkin and Schmidt have given saturation values of

98.5%; similar determinations carried out on normal human subjects gave figures as high as 98% to 99.3% (16, 17). They concluded that determinations performed by the usual gasometric techniques are too low by about 2% or more.

Ammundsen has shown that normal blood may contain "inactive hemoglobin" equivalent to as much as 2.5 vol.% CO capacity (18). In analyzing the errors of the gasometric method Roughton, Darling, and Root conclude that traces of COHb, which dissociate slightly during oxygenation to increase the effective oxygen capacity, and the conversion to normal hemoglobin of some of the "inactive hemoglobin" described by Ammundsen together with other minor factors give readings which are too low by about 2% (19).

In 12 cases studied at the onset of this investigation, a total of 16 oxygen saturation determinations from ear blood and six from the radial artery were made and the results were very low with an average of 86.2% (Table VI). Only two of the ear determinations were within the normal limits (95.5% and 96.1% O₂ saturation); the remaining 14 results ranged from 84% to 92%. The arterial oxygen saturation results in

six of these cases done at the same time ranged from 83.5% to 88% with a mean of 83.6%. Subsequent determinations in four of these cases revealed normal oxygen saturation results. It was later demonstrated that these low results were due to the fact that the blood was permitted to stand for hours before the oxygen capacity was determined. Correcting this error in technique increased the values and brought the oxygen saturation determinations closer to normal. In polycythemia vera there is an increase in total circulating red cell mass and thus probably an increase in carboxyhemoglobin and in inactive hemoglobin. Unless the O₂ content and capacity determinations are done shortly after withdrawal of the blood, there may be a release of the formerly unavailable hemoglobin with a consequent increase in the oxygen capacity leading to an erroneously low value for the oxygen saturation.

It seems apparent that in the resting patient with polycythemia vera, there is no great deficiency in the saturation of the circulating hemoglobin with oxygen. The values for the oxygen saturation in all the conditions studied except secondary erythrocytosis probably fall within normal limits.

There is an increase in oxygen content and capacity which is proportional to the increased circulating red cell mass. Where the hematocrit is normal, the oxygen content and capacity are similarly normal and the oxygen saturation is about 95%. There of course remains the possibility that during exercise there is significant unsaturation as suggested by Harrop and Heath (3) and this question is now under investigation in this laboratory.

SUMMARY

(1). Arterial blood oxygen saturation in polycythemia vera is within the limits of normal in the resting subject. (2). Low oxygen saturation results may be due to many factors amongst which are the inherent errors of any gasometric technique as well as the presence of traces of carboxyhemoglobin and inactive hemoglobin. (3). Gasometric oxygen determinations must be done soon after the blood is taken to prevent erroneously low oxygen saturation results.

THE PHOSPHORUS TURNOVER OF CARCINOMA OF THE HUMAN STOMACH AS MEASURED WITH RADIOACTIVE PHOSPHORUS¹

By JOHN SCHULMAN, JR.,² MARLENE FALKENHEIM,³ AND SEYMOUR J. GRAY

(From the Biophysical Laboratory and the Department of Medicine, Harvard Medical School, and the Medical Clinic of the Peter Bent Brigham Hospital, Boston)

(Received for publication May 27, 1948)

INTRODUCTION

The phosphorus turnover of tumors has been widely studied in animals and has been found to be higher than in normal tissues. Several blood dyscrasias have also been investigated extensively (1-3). The high uptake of radiophosphorus by leukemic cells and by red cells in polycythemia vera has been applied to the treatment of these diseases (4, 5). Low-Beer and collaborators have observed an increased uptake of radiophosphorus by human breast carcinomas as measured through skin *in vivo* (6); but they have derived no information about turnover. Since no studies have been made of the turnover of phosphorus in naturally occurring human cancers, we thought it of interest to investigate the phosphorus turnover of carcinoma of the human stomach, one of the most common of human malignancies. Because phosphorus takes part in so many reactions of the body, it also seemed of interest to determine whether any change in phosphorus metabolism was related to any particular group of compounds. Therefore, the turnover of the acid soluble, lipid, and protein phosphorus fractions was determined independently. The possible existence of quantitative differences in the phosphorus content of normal tissue and of tumor tissue was also investigated.

METHODS

These studies were made on patients undergoing subtotal gastrectomy, either for malignancy of the stomach or for non-malignant duodenal or gastric disease. The pathological diagnoses and other pertinent data are recorded in Table I. All patients were under the routine care of the surgical service and received blood transfusions and other intravenous medication as indicated.

¹ This work was supported in part by the Office of Naval Research.

² 1st Lt., MC, AUS. Present Address: Los Alamos Scientific Laboratory of the University of California, Box 1663, Los Alamos, New Mexico.

³ Present Address: Radiation Laboratory, University of California, Berkeley 4, California.

Radioactive phosphorus as $\text{KH}_2\text{P}^*\text{O}_4$ was furnished by the Clinton Laboratory at Oak Ridge, Tennessee, and solutions were prepared and standardized by R. F. Cowing of the New England Deaconess Hospital. The original sample was suitably diluted with distilled water and autoclaved. This neutral solution was administered intravenously approximately 36 hours prior to the scheduled time of operation. The chosen dose of 1 microcurie per pound of body weight was based on calculations by Cowing (7) which showed that this would lead to a total body irradiation of not more than 1.5 r.

Within one hour after removal of the stomach the mucosa was stripped from the stomach wall and prepared for analysis. In the non-cancerous stomachs mucosa was taken from the greater curvature, lesser curvature and pre-pyloric area; duodenal samples were obtained whenever possible. In the tumor-bearing stomach the position of the lesion was usually such that normal samples of all the areas could not be obtained. Consequently, a sample of normal appearing mucosa as far from the lesion as possible was taken. Histological study later showed that there were no malignant cells in the areas taken as non-cancerous. In the ulcerating tumors the samples were taken from the actively growing edge of the lesion.

The following analyses were performed:

Total phosphorus: 300 mg of tissue were dried in an oven at 110° C for two to three hours and then digested with 10 N H_2SO_4 and superoxol.

Acid soluble phosphorus (inorganic phosphate, ester phosphate, adenylic acid, adenosine diphosphate, adenosine triphosphate, creatine phosphate, etc.): 400 mg of tissue were minced with scissors and ground with 10% trichloroacetic acid in a small glass Potter-Elvehjem tissue homogenizer.⁴ The filtrate was digested with 10 N H_2SO_4 and superoxol.

Lipid phosphorus (lecithins, cephalins, sphingomyelins, etc.): 500 mg of tissue were finely minced with scissors and ground in the homogenizer with 1:1 ethyl alcohol-ether mixture. The homogenate was then extracted with two successive portions of alcohol-ether mixture on the steambath for periods of 30 minutes each. The combined extracts were evaporated to dryness and digested with 10 N H_2SO_4 and superoxol.

Protein phosphorus (chiefly nucleoprotein, but includes some phosphoprotein which does not yield nucleic acid upon hydrolysis): This fraction was calculated as the difference between the total phosphorus and the sum of the acid soluble and the lipid fractions.

⁴ Made to specifications by Macalaster Bicknell Company, Cambridge, Mass.

						No normal gastric mucosa

After the digestion, each sample was diluted to a suitable volume and aliquots were taken of the same sample for counting in solution with a Geiger-Mueller dipping counter (8) and for determination of the phosphorus content by the method of Fiske and SubbaRow (9). The errors of the chemical determination were about 5%, while the counting errors were as high as 10%. The protein phosphorus values, being calculated as differences, have larger errors than the other determinations. Values given in the tables represent averages of duplicate determinations.

Expression of results: Results have been expressed as Biological Concentration Coefficient (10)

$$BCC = \frac{\text{counts per min found in sample/mM}}{\text{counts per min injected/gm body weight}} \times 100.$$

This value is a coefficient and has no dimensions.

All data have been analyzed statistically; Fisher's "t" test was used throughout as a criterion of significance (11).

RESULTS

Phosphorus content: The possible existence of quantitative differences in the phosphorus content of normal gastric mucosa and of cancers was investigated. Table II shows the phosphorus content of the several areas of non-malignant stomachs. Applying Fisher's "t" test to the data in the table, we find that they are statistically homogeneous, i.e., there is no value that varies from the mean of the series by more than could be accounted for by chance. Therefore, the average of these results

* Mean of all non-cancerous mucosa, regardless of whether stomach bears a cancer.

may be considered to be the mean phosphorus content of the stomach, irrespective of the area of origin.

Table III shows the mean phosphorus content of all the stomachs studied. When non-cancerous stomachs are compared with the non-cancerous portions of cancer-bearing stomachs, there is again no demonstrable difference in the phosphorus content. Therefore, all the non-cancerous mucosae have been grouped as controls and compared with the cancer tissue. The difference in

the means of the cancer and the control group is insignificant. Thus, the phosphorus content is the same for all the tissues studied, whether normal or malignant. The same results are found when each of the phosphorus fractions is studied individually.

Biological concentration coefficient: When the Biological Concentration Coefficient after the injection of radioactive phosphorus is studied, however, a difference between cancer and non-cancerous mucosa can be demonstrated. The Biological

* Mean of all non-cancerous mucosa, regardless of whether stomach bears a cancer.

FIG. 1. BIOLOGICAL CONCENTRATION COEFFICIENTS OF PHOSPHOROUS COMPOUNDS IN NON-CANCEROUS GASTRIC MUCOSA AND IN CANCER-BEARING STOMACHS

The dotted lines represent means. C—cancer; NC—non-cancerous gastric mucosa. Each bar represents a patient.

Concentration Coefficients of the various regions of the normal stomach are the same. The use of an average value is therefore justified (Table IV). Furthermore, there is no significant difference between the non-cancerous mucosa from the cancer-bearing stomach and the mucosa from a stomach that does not bear a cancer (Table V). Therefore, all the non-cancerous samples of mucosa are grouped together regardless of presence or absence of cancer in other parts of the stomach, and their average Biological Concentration Coefficient compared to that of the cancer. This comparison (Figure 1) shows an increase in the Biological Concentration Coefficient of the total phosphorus of 47% over the normal ($p < 0.01$). The increase in the Biological Concentration Coefficient of the acid-soluble phosphorus is insignificant, but the 43% increase in the lipid phosphorus and the 124% increase in the protein phosphorus fractions are both statistically significant ($p < 0.01$ and $p = 0.02$, respectively).

DISCUSSION

Since this work was undertaken to study the turnover of phosphorus, *i.e.*, the replacement of phosphorus present by new phosphorus, it was necessary to express results in terms of specific activity—counts per millimole of phosphorus.

Because the radioactivity of a tissue will vary with the administered dose, counts were expressed as fractions of the injected dose. To avoid calculating the decay of the material, the dose was calculated from a standard solution counted on the same day as the samples. It was expressed in terms of body weight in order to compare different patients on the basis of equivalent doses. The factor of 100 is arbitrary. This expression we call Biological Concentration Coefficient.

$$\text{BCC} = \frac{\text{Cpm found in sample/mM P}}{\text{Cpm injected/gm of body weight}} \times 100.$$

The use of this expression is discussed at length elsewhere (10).

The expression Biological Concentration Coefficient has two important properties. It has no dimensions and it is not additive. One cannot add the Biological Concentration Coefficient of the acid-soluble fraction to that of the lipid fraction and that of the protein fraction and arrive at the value for the Biological Concentration Coefficient of the total phosphorus.

Phosphorus content: As pointed out previously, no differences were found in the phosphorus content of normal tissue and of the tumor. This is in contrast to the work of Kishi, Fujiwara, and Nakahara (12) who reported that the lipid phosphorus in experimental hepatomas was markedly decreased. Lustig (13) found a low lipid phosphorus content in human lung tumors and a high inorganic and protein phosphorus content. Whether this discrepancy is due to a species difference or a difference in the type or site of tumors studied is impossible to say.

Turnover: It has been shown that the constituents of a tissue are not static. There is a continuous building up and breaking down of tissue. When a tissue remains of constant size, as many atoms of an element must be lost as are being added. The ratio of the atoms added per unit of time to the total atoms of that element present in the tissue is known as the rate of turnover (14). Although this value cannot be determined absolutely except in special cases, relative rates of turnover can be estimated by comparing Biological Concentration Coefficients.

As labeled atoms are incorporated into a tissue their concentration rises rapidly and linearly at first and then slowly levels off to a maximum value. The maximum will be approximately the same for all tissues (15). During the linear portion of the uptake curve the amount of tracer in the tissue will be proportional to the number of new atoms being added, since the number of labeled atoms present is so small that their loss is negligible compared to the total number lost. Therefore, when radioactive phosphorus is administered to a patient and the Biological Concentration Coefficient is determined soon thereafter, the Biological Concentration Coefficient is proportional to the phosphorus turnover during the experimental period.

In practice we cannot assure ideal conditions. The size of the tissue remains constant within the limits of our experimental error. The ratio of tagged to untagged atoms in the plasma is not constant, but our expression has been so devised that the rate of change is probably the same in all subjects. The ideal time to measure the activity of the tissue (if one could obtain countable samples) would be immediately after injection of the isotope. At this time only a few atoms have been incorporated and the Biological Concentration Co-

efficient will be absolutely proportional to turnover. After this, the uptake curve starts slowly to level off and the Biological Concentration Coefficient will always be less than this value, *i.e.*, it will represent a minimum value. Thus, the differences found are minimum differences, although they approximate the true values.

The rate of phosphorus turnover is at least 45% higher in gastric cancer than in non-cancerous gastric mucosa. This is in accord with the results found in tumors in experimental animals (1-3).

When the acid-soluble phosphorus compounds were studied the turnover rates in cancer and non-cancerous mucosa were found to be essentially the same.

The lipid phosphorus turnover is at least 45% higher in the tumor than in the non-cancerous tissue. Cell phospholipids are present usually as structural cell components so that this increased turnover probably represents a more rapid cell formation and destruction.

The phosphoproteins—chiefly nucleoproteins—are principally cell building blocks. Therefore, the 124% increase in the phosphoprotein turnover as compared to normal turnover probably results from enhanced tissue synthesis. Brues, Tracy, and Cohn (16), studying regenerating liver and hepatoma in the rat, found an increased uptake of phosphorus in nucleic acids and found this to be due chiefly to the desoxyribose nucleic acid, the compound present chiefly in the cell nuclei.

There are two possible ways of explaining the increased growth of a tissue. All tissues are continually breaking down old cells and replacing them with new ones. Normally, in the adult tissue the rates of anabolism and catabolism are equal, so the tissue does not change in size. When a tissue is growing, however, this balance is upset. Either formation of new tissue is enhanced or breakdown of old tissue is inhibited. An increased phosphoprotein Biological Concentration Coefficient represents increased synthesis of phosphoproteins.

Histological evidence of increased mitotic activity would indicate that new cells are being formed. However, new cells might be formed from pre-existing proteins, so that mitotic activity does not necessarily prove that new proteins are being synthesized. Friedberg and collaborators (17) investigated the incorporation of glycine into the tissues of developing embryos and found a high

rate of anabolism. Rittenberg, Sproul, and Shemin (18), on the other hand, studying the incorporation of labeled glycine into proteins of regenerating liver, found that it was incorporated at about the same rate as into the proteins of resting livers. From this they concluded that the mechanism of increasing size was the inhibition of the breakdown of tissue. When studying transplanted rat sarcomas, their results were equivocal (19).

Our results tend to agree with those of the former group since the tumor tissues are synthesizing phosphoproteins at more than twice the normal rate. Catabolism must also be increased to some extent, since the increased rate of turnover is much higher than the observed rate of growth. These experiments then, tend to show that the increasing size of a tumor is due to the increased building of cell constituents and an increased breakdown which, however, is not rapid enough to maintain a constant normal size.

Clinically, it has been recognized that on some portions of the stomach, such as the pre-pyloric area and the greater curvature, cancer is common. On the other hand, cancer is less common on the lesser curvature, and is very rare in the duodenum. No satisfactory explanation has been advanced for this. The possibility suggested itself that in the absence of cancer, the regions in which cancer is common had a metabolism more like cancer than did those regions where cancer is rare. The results of studying the few non-cancerous stomachs available tend to show that the rates of phosphorus turnover in all areas of the stomach are the same. Of course, completely normal stomachs are not available as operative specimens.

Another common clinical observation is that cancer of the stomach and atrophic gastritis occur together more frequently than would be expected from their occurrence alone in the general population. This has led to the suggestion that atrophic gastritis might be a precancerous lesion. If this were true, one might expect that the atrophic mucosa would show chemical or metabolic properties intermediate between the cancer and the normal. Cowdry (20) observed this to be the case with many properties of experimental and naturally occurring cancers of the skin. To investigate this possibility the uninvolved mucosa of cancer-bearing stomachs (usually showing atrophic gastritis) was compared with the mucosa of non-cancer-bearing

ing stomachs. At least in regard to the rate of turnover of phosphorus, no difference could be observed. The evidence tends to show that the malignant type of metabolism is limited to the confines of the tumor itself, and that the rest of the mucosa behaves normally.

SUMMARY

The phosphorus content and the rate of phosphorus turnover of non-cancerous gastric mucosa and of gastric carcinoma have been measured with the aid of radioactive phosphorus.

1. The rate of turnover of phosphorus by gastric carcinoma is at least 45% higher than by non-cancerous gastric mucosa.

2. There was at least a 124% increase in the turnover of protein phosphorus and at least a 45% increase in turnover of lipid phosphorus; the acid-soluble phosphorus turnover remained unchanged.

3. The increased rate of phosphorus turnover is limited to the cancer itself and is not demonstrable in the surrounding tissue.

4. In the non-cancerous stomach there are no differences in those areas in which cancer is common and in those in which it is rare.

5. There is no difference in the phosphorus content of cancer of the stomach and non-cancerous gastric mucosa.

ACKNOWLEDGMENTS

The authors wish to thank Dr. A. K. Solomon for designing the counting equipment, and Mrs. J. Harris and Mrs. M. J. McDonald for the determination of the radioactivity of the samples. We are grateful to Dr. DeWitt Stetten, Jr., for his advice and helpful discussions. We also wish to acknowledge the cooperation of Dr. J. Englebert Dunphy, Dr. Francis C. Newton, Dr. James Blodgett and other members of the surgical service for the gastrectomy specimens.

CHEMICAL, CLINICAL, AND IMMUNOLOGICAL STUDIES ON THE
PRODUCTS OF HUMAN PLASMA FRACTIONATION.
XXXVII. THE METAL-COMBINING GLOBULIN
OF HUMAN PLASMA¹

By DOUGLAS M. SURGENOR, BERNARD A. KOECHLIN,²
AND LAURENCE E. STRONG³

(From the Department of Physical Chemistry, Harvard Medical School, Boston)

(Received for publication June 14, 1948)

The separation of the proteins of human plasma into a series of fractions and subfractions, uniform with respect to certain physical properties, has generally led also to the separation of proteins with respect to their chemical and biological properties. Among the properties that have long been recognized has been the binding of metals by the plasma so that the metals were no longer freely dialyzable (1). When plasma fractionation was undertaken, early in the war, the Committee on Blood Substitutes of the National Research Council were informed that "investigations of the distribution of . . . metals known to be combined with proteins in the blood, such as copper, zinc, and iron, are planned and will be subsequently reported, as will studies upon the hormones and other physiologically important components of human plasma for which methods of bio-assay are available. We feel keenly that these should now be studied in the large amounts of human plasma fractions becoming available as by-products of the preparation of human albumin for transfusion in shock" (2).

¹ This paper is No. 72 in the series "Studies on Plasma Proteins" from the Harvard Medical School, Boston, Mass., on products developed by the Department of Physical Chemistry from blood collected by the American Red Cross. This work was originally supported by grants from the Rockefeller Foundation and from funds of Harvard University. It was aided early in 1941 by grants from the Committee on Medicine of the National Research Council, which included a grant from the American College of Physicians. From August 1941 to July 1946 it was carried out under contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University. Since then it has been aided by a grant recommended by the Panel on Hematology of the National Institute of Health.

² Present address: Sloan-Kettering Institute, New York, N. Y.

³ Present address: Kalamazoo College, Kalamazoo, Michigan.

Clinical studies had suggested not only that there was a binding of iron and copper, but that there might be a relation between iron and copper binding by the plasma proteins in the sense that an increase in the concentration of the one metal in the plasma was often associated with a decrease in the other (3-5).

The next advance in our knowledge of the binding of metals by proteins followed bacteriological investigations upon egg white. Schade (6) reported that the growth of the bacterium *Shigella dysenteriae*, which requires iron for its metabolism, was readily inhibited by egg white. The same phenomenon of inhibiting bacterial growth by the binding of iron by protein was next noted as a result of studies upon human plasma (7). Fractions of human plasma were made available to Schade, at his request, and the property of bacterial growth inhibition found to be completely concentrated in the fraction that had been designated IV-4 (8).

The methods of detecting this protein component colorimetrically that were being developed by Schade were adopted, with slight modifications, for our studies, and led to the concentration of the iron-binding protein component of plasma into a new fraction (IV-7) (9), and finally to its crystallization (10).

This component of plasma has been designated the β_1 -metal-combining globulin because of *in vitro* evidence, obtained with the crystallized protein, that it is capable of binding copper and zinc, as well as iron. The clinical and physiological studies reported in this series of communications have been carried out with Fraction IV-7, which is readily prepared in large amounts as a by-product of the fractionation of human plasma to yield serum albumin, γ -globulin, fibrinogen, thrombin and other stable blood derivatives, rather than with the more highly purified crystallized protein.

Fraction IV-7 consists to the extent of 76 per cent of the metal-combining protein; the inert components being mainly albumin and an α_2 -globulin.

MATERIALS AND METHODS

The Fraction IV-7 and crystallized β_1 -metal-combining globulin used in these studies were prepared from Fraction IV-4 from blood collected by the American Red Cross by methods to be described elsewhere (8, 9).⁴

Carbohydrate analyses were performed by a modification of the method of Sørensen and Haugaard (11), using orcinol. An equimolar solution of mannose and galactose was used as the standard.⁵ Electrophoretic analyses were made in 0.1 ionic strength sodium diethyl barbiturate buffer at pH 8.6.⁶

Assays for metal-combining activity were made with a modification of the method of Schade and Caroline (7) by spectrophotometrically determining the colored iron-protein complex. To aliquots of a solution of the protein in pH 7.4, ionic strength 0.1 barbiturate buffer were added different amounts of a standard solution of ferrous ammonium sulfate. After standing 60 minutes at room temperature the optical densities of the solutions were read in the Beckman spectrophotometer at a wavelength of 465 m μ . On plotting optical density as a function of iron added, it was found that the extinction increased linearly to a maximum after which it remained substantially constant. The intersection of the two straight lines plotted through the points was taken as the most accurate estimate of the combining capacity. We are greatly indebted to Dr. Schade for his continuing collaboration as well as for periodic microbiological assays which confirmed the results of the spectrophotometric determinations.

RESULTS

A. Studies with the crystallized β_1 -metal-combining globulin

The isolation of a pure crystallized protein with all the chemical and physiological properties of the metal-combining globulin proved the identity of the protein. We have therefore based our stud-

ies on the properties of the crystallized globulin. The behavior of less pure concentrates of the globulin, such as Fraction IV-7, should differ only quantitatively with respect to properties attributable to the specific component interacting with iron or other metals. Those properties observed with a concentrate, not attributable to the pure globulin, should therefore be attributed to impurities in the concentrate removed during the further purifications and crystallization.

1. Physical and chemical properties

Electrophoretically, the metal-combining globulin is characterized as a β_1 -globulin. The protein of plasma has been estimated to contain 11 per cent of β_1 -globulins (12) of which approximately 3 per cent is the metal-combining protein. The latter differs in size, shape, solubility, and composition, from the other β_1 -globulins of the plasma which are largely separated into Fraction II + III (13). The metal-combining globulin resembles the albumins more than most of the other globulins in its solubility behavior and its stability under a variety of conditions of pH, ethanol concentration and temperature. Unlike the albumins, it is in an isoelectric condition near pH 5.9. The sedimentation constant, $S_{20, w} = 5.0$, and molecular weight of 90,000 indicates a molecule of somewhat larger dimensions than the albumins (10, 14). The metal-combining globulin contains but a negligible amount, if any, of lipid. Its carbohydrate content has been estimated to be 1.8 per cent. The nitrogen content was 14.7 per cent, corresponding to a nitrogen factor (gm. protein/gm. nitrogen) of 6.82. The latter is somewhat higher than that of the albumins and many other proteins, and undoubtedly reflects the presence of carbohydrate in the molecule.

2. Interactions with iron

Solutions of the complex formed between the crystallized globulin and iron exhibited the salmon red color which Schade (6, 7) had observed to be characteristic of fractions of plasma active with respect to the microbiological test, and indeed, of the iron-binding protein of egg white. The visible absorption spectrum of the iron-protein complex, measured against a protein blank, is represented

⁴ Certain of the preparations of Fraction IV-4 were derived from out-dated dried plasma, being fractionated for the American Red Cross by E. R. Squibb and Sons, New Brunswick, New Jersey, and were released by the American Red Cross for this investigation. For other preparations of Fraction IV-4, fractionated from fresh plasma by the Division of Biologic Laboratories, Massachusetts Department of Public Health, we are indebted to Drs. V. A. Getting, G. Edsall, and D. J. Mulford.

⁵ We are grateful to Dr. D. M. Gibson and Mr. Robert S. Gordon, Jr., for the carbohydrate analyses.

⁶ We are indebted to Mr. M. J. E. Budka and Miss M. M. Hasson for these measurements.

in Figure 1.⁷ The broad absorption band had its maximum at 465 $m\mu$, with $E_{1\text{ cm.}}^{1\%} = 0.570$.⁸ This band was the basis of the spectrophotometric determination of iron-binding capacity, described previously. The width of the band allowed use of a number of wavelengths other than the maximum for the determination. Thus, Rath and Finch (15) have used the absorption at 525 $m\mu$ in their titrations of serum to avoid interference by other substances present which absorbed at shorter wavelengths.

FIG. 1. ABSORPTION SPECTRA OF METAL-COMBINING GLOBULIN IN PRESENCE OF IRON AND COPPER, MEASURED AGAINST A PROTEIN BLANK: Solid line—COMPLEX WITH IRON, pH 7.4, $I/2$ 0.1 BARBITURATE; dashed line—COMPLEX WITH COPPER, pH 8.5, $I/2$ 0.05 BARBITURATE

Neither the iron-free globulin nor iron alone absorbed appreciable amounts of light at these wavelengths and in the concentration range used. Indeed, the formation of a colored complex with iron was a unique property of the metal-combining globulin, to the exclusion of all the other plasma proteins. This was confirmed by observation of the migration of a solution of the complex in the Tiselius apparatus at pH 8.6. The color was found to move in sharp coincidence with the peak

of the protein Schlieren diagram throughout the duration of the experiment.

The reaction between iron and the metal-combining protein was dependent on pH. At neutral pH, above pH 6.5, the color and interaction were maximal. On acidification the color diminished, and below pH 5 the iron could be dialyzed from the solution. The dissociation of the complex and the loss of color were readily reversed by readjusting the system to pH 7. This dependence of the metal-protein interaction on pH is represented in Fig-

FIG. 2. SPECTROPHOTOMETRIC BEHAVIOR OF METAL-COMBINING GLOBULIN IN PRESENCE OF EXCESS IRON AS A FUNCTION OF pH

Iron (as $\text{FeSO}_4 \cdot [\text{NH}_4]_2\text{SO}_4 \cdot 6\text{H}_2\text{O}$) 2.8 γ/mg . Fraction IV-7. Measured against protein blank.

ure 2. The experimental points were obtained by titrating aliquots of an acidified solution of Fraction IV-7, containing ferrous ammonium sulfate, with alkali in the absence of buffer. The amount of iron in each aliquot was the same and corresponded to approximately two-fold excess over that which could be bound to the protein at the pH of maximum binding. The optical density and pH of each aliquot were measured after standing overnight at 5° C.⁹

⁷ Preliminary studies suggest that in the ultraviolet region, iron produces a non-specific enhancement of the usual protein absorption near 280 $m\mu$. This has been observed also with bovine serum albumin.

⁸ The extinction coefficient, $E_{1\text{ cm.}}^{1\%}$, is a constant at any given wavelength, and is defined by the expression: $\log I_0/I = E_{1\text{ cm.}}^{1\%} \cdot c \cdot l$, where $\log I_0/I$ is the optical density, c , the concentration in gm./100 ml. , and l , the length of the path of light through the solution in the cuvette, measured in cm. This is the familiar Beer-Lambert equation.

⁹ We have not attempted to evaluate the mass law equilibrium constant for the interaction because of the number of variables involved. However, at neutral pH, under conditions of maximum combining capacity, the interaction of the protein with iron was practically independent of the concentration of free iron in solution. Were this not so, the titration curve of the protein with iron would not have shown the sharp "break" at the point of saturation. At acid pH, this was not so, and the titration curves were of sigmoid shape.

The crystallized globulin was capable of binding 1.25 γ of iron per milligram of protein. This corresponded to two atoms of iron per molecule of protein of molecular weight 90,000. Although we have preferred to use ferrous salts for studying the interaction, iron in the form of ferric salts also interacted with the protein. The complex so formed was identical in its spectral absorption to that formed by the use of ferrous salts. The interaction with ferric salts was much slower, however, possibly because of their lower solubility and more rapid hydrolysis at neutral pH. Further evidence of the identity of the complexes formed with ferrous and ferric iron was obtained by Dr. Michaelis (16), who measured the magnetic susceptibility of the complex formed between the crystallized metal-binding globulin and ferrous ammonium sulfate. The results indicated that the iron in the complex is in the ferric state and that the complex is ionic, not covalent. It is therefore evident that the ferrous iron was oxidized prior to or during the formation of the complex with the protein.¹⁰

The iron-binding capacity of Fraction IV-4, or any of its subfractions which contained metal-binding globulin, has always been found equal, within the limit of error achieved, to the expected iron-binding capacity of the crystallized material on the assumption that all of the electrophoretically determined β_1 -globulin in the fraction was the metal-combining globulin. Since no other fraction of plasma contained measurable quantities of the globulin, *we estimate that normal plasma contains 2.4 gm. per liter of this component, capable of binding a total of approximately 3 mg. of iron per liter.* This is in good agreement with the value of 315 γ per 100 ml. found by Rath and Finch (15).

3. Interaction with copper

The crystallized metal-combining globulin also interacted with copper in a manner similar, in most

respects, to the reaction of the globulin with iron. The copper-protein complex had a green color whose absorption spectrum has been represented in Figure 1. The maximum was near 435 $m\mu$ with $E_{1\%}^{1\text{cm.}} = 0.45$. Copper-binding capacity was determined by titration with a standard solution of copper sulfate. A pH 8.4 barbiturate buffer of ionic strength 0.05 was used. Under these conditions each milligram of protein bound 1.4 γ of copper, corresponding to two atoms of copper per molecule of protein.

The interaction of copper with the crystallized globulin differed from that of iron in that the pH-binding curve for the copper was displaced approximately 1 pH unit toward alkaline reactions relative to that of iron. Maximum binding occurred near pH 8.5; at pH 7, where the protein had its maximum binding capacity for iron, its capacity to bind copper was only approximately half maximum.

It was of interest to study the relative affinity of the metal-combining globulin for copper and iron. Using the absorption spectra as an indication, no conditions have been observed under which copper displaced iron from the iron-protein complex. Further, below pH 8, iron displaced copper from the copper-protein complex. Copper and iron are therefore probably bound to the same groups on the protein molecule, the affinity for iron being higher at neutral pH.

Because of these results of *in vitro* studies we have designated this component of plasma the metal-combining globulin.¹¹ While the evidence from clinical studies (15, 18) has suggested that this protein is indeed responsible for the physiological transport of the iron in plasma, and the chemical studies have shown that this component was present in sufficient concentration to satisfy the iron-binding capacity of plasma, the evidence for the *in vivo* transport of copper is less clear. Thus, while chemical studies have shown that this component was capable of binding copper to a certain extent at physiological pH, they do not preclude the existence of a separate *in vivo* mechanism for the transport of copper.¹² Indeed, the binding of copper by albumins has been shown by Klotz (19).

¹⁰ Studies on the time necessary for full development of color suggested that autooxidation of ferrous iron was a prerequisite to binding (10). Thus, at pH 8, full color developed within a few minutes, whereas at pH 6.5, several hours were necessary. Schade, Reinhart and Levy (17) have found that carbon dioxide has a role in the formation of the complex. Other factors may be involved as well (22).

¹¹ This component has been called "siderophyllin" by Schade, Reinhart and Levy (17) and "transferrin" by Holmberg and Laurell (23).

¹² Since this manuscript was submitted, the work of Holmberg and Laurell (23) has come to our attention.

4. Interaction with other metals

Of a series of metals investigated, including cobalt, nickel, zinc, manganese, as well as copper and iron, only the latter two formed a complex with the protein, as characterized by an absorption of light. However, failure of formation of color cannot be considered as evidence of failure of complex formation. Thus zinc, which failed to produce a color when added to solutions of the metal-combining globulin, was nevertheless bound to the protein at neutral pH as shown by direct analysis for zinc.¹⁸ Studies on the interactions of the globulin with zinc and other metals will be the subject of later communications.

B. Properties of Fraction IV-7 of human plasma

In the subfractionation of Fraction IV-4, the metal-combining globulin was further purified and concentrated in Fraction IV-7, the fraction recommended for use in clinical studies on this component of plasma. The preparations which were fractionated at the Harvard Pilot Plant contained an average of 76 per cent of the metal-combining globulin. They differed with respect to this component only quantitatively from the crystallized material. Thus, Fraction IV-7 bound 0.8 to 0.9 γ of iron per milligram of protein.

The impurities in Fraction IV-7 were mainly albumin and α_2 -globulin. Certain properties of this fraction were due to these impurities and were absent in the crystallized metal-combining globulin. Among these were an ability to bind bilirubin (20) and hematin (21). The binding of bilirubin was higher than could be attributed to the albumin present, and was found to be a characteristic of the α_2 -globulin in the fraction. This latter component of Fraction IV-7 was thus responsible for the occasional presence of colored impurities in preparations of Fraction IV-7 derived from hemolyzed plasma. Highly colored samples from this source have, however, had unimpaired metal-binding capacities.

They confirm many of our findings and suggest further that the main part of the serum copper is normally associated with an α -globulin which is insoluble in 50% ammonium sulfate.

¹⁸ We are grateful to Dr. B. Vallee for the zinc analyses.

Solutions of Fraction IV-7 for clinical use have been made by dissolving the dried protein in isotonic saline at pH 6.8 in a concentration of 25 gm. of protein per 100 ml. of solution. Neither acetyl tryptophane, which has been used to stabilize solutions of albumin, nor glycine, which stabilizes γ -globulin solutions, were as effective as sodium chloride in stabilizing solutions of Fraction IV-7. Such solutions were capable of binding approximately 22.5 mg. of iron per 100 ml. and were therefore concentrated approximately seventy-fold over plasma with respect to the metal-combining globulin.

SUMMARY

1. A component of normal human plasma, the metal-combining globulin was concentrated in Fraction IV-7 and crystallized therefrom.
2. The metal-combining globulin is a β_1 -globulin and is distinct in its behavior and properties from other β_1 -globulins of plasma.
3. The capacity of this component of plasma to bind metal ions, particularly iron, copper and zinc, has been discussed. These interactions with metals were readily reversed by change in pH and, in the case of copper and iron, were characterized by the formation of colored metal-protein complexes with characteristic absorption spectra.
4. The protein had a higher affinity for iron than for copper in solution as judged by the capacity of the former to displace copper from the complex.
5. Fraction IV-7 derived from human plasma has been recommended as a concentrated source of the metal-combining globulin. Its safety for injection in man has been investigated and its properties reported.

SERUM IRON TRANSPORT. MEASUREMENT OF IRON-
BINDING CAPACITY OF SERUM IN MAN¹

By CHARLES E. RATH² AND CLEMENT A. FINCH³

(From the Department of Medicine, Harvard Medical School, and the Medical Clinic,
Peter Bent Brigham Hospital, Boston)

(Received for publication June 14, 1948)

Iron absorbed from the intestine, from destroyed erythrocytes, and from storage depots must be constantly redistributed via the blood stream to satisfy the needs of various body tissues. The studies of Heilmeyer and Plotner (1) and of Moore and his associates (2) indicate that the iron of the serum performs this function. It has been further established that this iron is protein-bound, since the iron is non-dialyzable (3), does not appear in the ultrafiltrate unless acidified (4) and is precipitable with the serum globulins (5).

Employing a micro-biological assay method, Schade (6) recently localized an iron-binding protein in Fraction IV-4 of Cohn and his associates. The crystallized protein (7) is a β_1 globulin⁴ with a molecular weight of approximately 90,000, and binds two molecules of iron per molecule of protein. The globulin itself is colorless but when combined with iron, develops a salmon red color. This color reaction described by Schade has been utilized in the measurement of the iron-binding capacity of normal and pathological sera.

METHOD

Schade (6) has shown that a progressive development of red color occurs on the addition of iron to this β_1 globulin until the protein becomes saturated. At the point of saturation there is a sharp break in the color

curve which corresponds to the exact point at which free iron may be demonstrated by bio-assay. The spectrophotometric absorption curve of this iron-protein combination has been described (8). A wave length of 525 $m\mu$ was arbitrarily chosen in our studies because of the greater color absorption of serum at shorter wave lengths. On each sample of serum a determination of serum iron and unsaturated iron-binding capacity was made.

Fasting venous blood is drawn without hemolysis into a syringe coated with mineral oil. The clotted blood is centrifuged at 2,000 r.p.m. for 15 minutes and the serum obtained is recentrifuged to remove all red cells. The Coleman Spectrophotometer, Model 11, and cuvettes of 1 cm. depth are used. One cuvette is filled with 5 cc. of 0.9 per cent saline, while in the other is placed 2 cc. of serum and 3 cc. of 0.9 per cent sodium chloride. Originally each cuvette was filled with serum, one serving as a blank. This was found to be unnecessary. Iron standard solution⁵ was added in 0.05-cc. quantities to both cuvettes and a glass stirring rod used to mix the contents of the cuvette after each addition of iron. Readings of per cent of light transmission are made two or three minutes after each mixing. The iron solution is added until there has been no change in the per cent transmission after three successive readings. The data are plotted on graph paper and the point of intersection of the two slopes is taken as the amount of iron necessary to saturate the iron-binding protein (Figure 1). Serum iron determinations were made according to the method of Kitzes, Elvehjem, and Schuette (9). It is possible to determine the total capacity of each sample of serum by totalling the serum iron and the unsaturated binding capacity.

The blood is drawn in the morning with the patient in the fasting state. Lipemic serum, severe icterus, and serum over 24 hours old, were found unsatisfactory. All glassware is carefully cleaned with concentrated nitric acid and glass-redistilled water to render it iron-free. All reagents used are likewise iron-free. Figure 2 shows

⁴ This β_1 globulin has been variously termed metal-combining globulin and iron-binding protein; the terms being used synonymously. *In vitro* evidence indicates that the protein is capable of combining with other metals (8). Since the only *in vivo* function of this protein thus far demonstrated is that of iron transport, reference to other metal binding will not be made in this paper.

⁵ Iron standard is prepared by diluting 14 mgs. of ferrous ammonium sulfate plus 0.5 cc. of 1 N acetic acid to 100 cc. This represents 20 gamma of iron per cc. of standard. Each standard solution is checked by direct iron analysis. Therefore, each addition of 0.05 cc. to 2 cc. of plasma represents an increment of 50 gamma per 100 cc. serum.

FIG. 1. DETERMINATION OF THE IRON-BINDING CAPACITY OF SERUM

the iron-binding capacity titration with known increments of crystalline iron-binding protein. Table I shows the measured as compared with the calculated increase in iron-binding capacity of serum upon the addition of increments of crystalline iron-binding protein. This method is readily adapted to a colorimeter with a filter of 525 $m\mu$.

RESULTS

Measurements of serum iron, unsaturated iron-binding capacity, total capacity and per cent satu-

ration on 30 normal subjects and 105 patients are shown in Table II, and the groups of particular interest are portrayed graphically in Figure 3. There was no significant difference between men and women. In the combined normal group, serum iron averaged 100 gamma, iron-binding capacity 200 gamma, and total capacity 300 gamma per 100 cc. of serum. Circulating iron-binding protein was 34 per cent saturated with iron. In iron

FIG. 2. IRON-BINDING PROTEIN TITRATION

The amount of iron required to saturate increments of the pure β_1 globulin was determined colorimetrically. Each point represents a single determination of iron-binding capacity. Each milligram of protein binds about 1.25 gamma of iron and the measurement is accurate within 25 gamma per 100 cc. When increments of β_1 globulin are added to plasma the same amounts are obtained with an accuracy of within 50 gamma per 100 cc.

MEASUREMENT OF IRON-BINDING CAPACITY OF SERUM IN MAN

81

TABLE I

Measurement of iron-binding capacity on addition of iron-binding protein to serum

Capacity per 100 cc. of serum	Iron-binding capacity per 100 cc. of crystalline protein added	Iron-binding capacity per 100 cc.	
		Anticipated	Found
gamma/100 cc.	gamma/100 cc.	gamma/100 cc.	gamma/100 cc.
I 100	30	130	140
100	60	160	170
100	90	190	180
100	120	220	235
100	150	250	265
100	180	280	275
100	210	310	300
100	240	340	350
II 250	75	325	330
250	150	400	400
250	225	475	455
250	300	650	630
250	375	725	720

In the table above, increments of crystalline protein of known iron-binding capacity were added to serum with a measured capacity of 100 (I) and to serum with a measured capacity of 250 (II). The increased iron-binding capacity of the serum as determined by the method herein described is compared with the anticipated new binding capacity representing the sum of the capacity of the serum plus the capacity of the added crystalline protein.

deficiency, while the serum iron was lowered, there was an increase above normal in both the unsaturated iron-binding capacity and total carrying capacity of the serum. This is to be contrasted with infection in which serum iron was similarly reduced but where the iron-binding capacity and total capacity were reduced as well. It is of interest that the saturation was below 10 per cent in eight out of ten cases of iron deficiency, while it was above 10 per cent in all ten cases of infection. In general, in patients with iron deficiency who also had carcinoma or other debilitating disease, the per cent saturation was still in the vicinity of 10 per cent, but the total capacity was not significantly increased. In a variety of conditions having in common only general debility and reduction in circulating plasma protein (cancer, infection, liver disease, and renal disease), there was a reduction in the iron-carrying capacity of the serum. Ten normal pregnant women showed no significant deviation from the normal during the first, second, or third trimester of pregnancy. A high serum iron and high percentage saturation of the iron-binding protein were found in refractory anemia, pernicious anemia, hemochromatosis, transfusion hemosiderosis, and liver disease.

Preliminary work has been carried out with Fraction IV-7 processed from human plasma by Surgenor and his associates (8). This material bound *in vitro* 1 mg. of iron per milligram of protein. It has been administered intravenously to 22 individuals in amounts of 2.5-5.0 gms. over periods of 15 to 30 minutes. In two patients, the injection was repeated after two weeks and in neither case was there any reaction. In general, the injections produced a slight rise in serum iron during the first four to six hours, but the maximum rise occurred after a latent period of 12 to 24 hours after injection. The increase in serum iron was as much as 115 gamma per 100 cc. of plasma. This fell over the following two to six days un-

less the patient had hemosiderosis or hemochromatosis, in which case the elevation was maintained over a longer period. A second injection of globulin given to the same patient did not produce a rise in serum iron level except in cases of iron excess.

DISCUSSION

The validity of this measurement of the iron-binding protein capacity of human sera would seem to be established in a number of ways: (1) the increased capacity produced by the addition of

FIG. 3. IRON-BINDING CAPACITY OF SERA

The iron-binding capacity of human serum is represented in block diagram. The cross-hatched portion represents serum iron, and the clear area the unsaturated capacity of the iron-binding protein in gamma per 100 cc.

known amounts *in vitro* of pure iron-binding globulin to plasma may be measured with an error of less than 50 gamma per 100 cc.; (2) the intravenous injection of iron-binding protein results in an increase in the measured binding capacity proportionate to the amount of protein given; (3) injections of iron or of nonviable erythrocytes will result in increase in serum iron to the point of total binding capacity as previously measured but not beyond it; (4) those patients with saturation of their iron-binding protein show no significant increase in serum iron after oral or intravenous iron administration.

The observation that serum iron cannot be increased above the measured saturation point of the globulin confirms other evidence that iron cannot exist in a free state in the serum. The only exceptions to this are the injections of massive amounts of iron ascorbate (10) or iron ascorbate gelatin complexes and the serum of terminal hemochromatotic patients where very high levels of serum iron may be found. It would appear in both of these instances that the iron is bound to some other protein complexes. This complete protein binding of iron in the body, whether intracellular

or within the blood stream, probably explains the inability of the body actively to excrete iron.

Holmberg and Laurell (11) have reported similar measurements of the iron-binding capacity of serum, employing a different method dependent on the color reaction between dipyrldyl and unbound iron. In normal subjects the serum iron averaged 130 gamma per 100 cc. and the total capacity was 312 gamma per 100 cc. These figures are in good agreement with our data. As pointed out by these authors, the increase in serum iron and the maximum level attained following oral and intravenous iron tolerance tests are limited by the amount of iron-binding globulin in circulation. For example, the initial height of 291 gamma per 100 cc. observed by Waldenstrom (12) following intravenous injection of iron in normal subjects was very close to the total capacity as measured by Holmberg and Laurell and by us. The lower average level obtained by Wintrobe of 168 gamma per 100 cc. (13), in patients with infection after intravenous iron, again is consistent with the reduced binding capacity found in our group with infection.

The lack of response of serum iron in patients

with untreated pernicious anemia or hemochromatosis to oral iron administration is considered to be due to the pre-existing high degree of saturation of the β_1 globulin which will allow little or no increase in serum iron. The unaltered level of serum iron does not, however, preclude iron absorption, since the serum iron level is not an expression of the turnover rate of iron in the serum. This will be the subject of a later report.

The total binding capacity of normal sera of about 300 gamma per 100 cc. represents about 250 mgs. of iron-binding protein per 100 cc. of plasma.⁶ Increases in iron-binding protein were observed by us in iron deficiency, and have been reported by Laurell (14) in pregnancy. These increases parallel the need of the body for more efficient iron absorption and transport. Further work is necessary to determine whether this increase in iron-binding protein is responsible for the increased iron absorption in these conditions. In other conditions decreases in total binding capacity to 50 per cent of normal have been observed, but it seems improbable that this reduction in any instance was capable of significantly impairing iron transport since there was an appreciable amount of unsaturated iron-binding protein still in circulation.

It would appear that the level of serum iron and the per cent saturation of the iron-binding protein are carefully regulated under normal circumstances. Conditions in which saturation of iron-binding protein is increased are those involving bone marrow block, iron excess, and severe liver disease. The important role of the liver in serum iron regulation is not unexpected since this organ is the chief iron storage depot of the body. Whether or not conditions of iron excess may be recognized without some degree of hepatic dysfunction is not yet clear. At any rate, it has been possible to make the diagnosis in nine cases of hemochromatosis by this technique and to separate these cases from simple cirrhosis. Depression of the per cent saturation occurs in iron deficiency and in infections. It seems reasonable to explain the former on the basis of depletion of body iron and the latter on an increased affinity of tissue storage depots for iron (15).

Laurell (14) in a very comprehensive and excellent study of iron transport has repeated meas-

urements of the iron-binding protein in a variety of conditions. Although different methods were used, the results we have obtained are in perfect agreement with those of Laurell. We hesitate to accept the hypothesis that the degree of saturation may regulate iron transport and iron absorption. For example, in animals on diets which allow excessive iron absorption, the serum-binding protein becomes completely saturated with iron after about two weeks, yet iron absorption continues fully as rapidly over the following three to four weeks (16). Movement of iron within the body may be managed by the respective affinity of various tissues for iron, in which system the carrier protein of the serum would play a passive role. Injections of iron-binding protein exert only a very temporary effect on the serum iron level. It remains to be determined how much one may aid or interfere with iron transport by increasing or decreasing the amount of iron-binding protein.

SUMMARY

A method is described for the measurement of the iron-binding capacity of human serum. Measurements of serum iron, total iron-binding capacity, and per cent saturation of this protein are reported in normal subjects and in a variety of diseases. The implications of these findings are discussed.

ACKNOWLEDGMENT

The authors wish to express their appreciation to Doctor Cohn and his associates for the materials used in part of this study.

CHEMICAL, CLINICAL, AND IMMUNOLOGICAL STUDIES ON THE
PRODUCTS OF HUMAN PLASMA FRACTIONATION. XXXIX.
THE ANEMIA OF INFECTION. STUDIES ON THE
IRON-BINDING CAPACITY OF SERUM¹

By G. E. CARTWRIGHT AND M. M. WINTROBE

(From the Department of Medicine, University of Utah, School of Medicine, Salt Lake City)

(Received for publication June 14, 1948)

It has been generally recognized since Barkan's original observations in 1929 (1) that the iron in serum is non-dialyzable and non-ultrafilterable at pH 7.3 and, therefore, is probably protein-bound (2-4). To which of the serum proteins the iron is bound was not clearly established until recently. Earlier work indicated that half-saturation with ammonium sulfate precipitated serum iron quantitatively together with the globulins (5). Vahlquist (4) with the aid of the electrophoretic technique concluded that the iron in serum is bound to both albumin and globulin, the α and β globulins serving as the principal carriers.

Following their demonstration of a protein component in raw egg white capable of binding iron (6), Schade and Caroline investigated various fractions of human plasma prepared by E. J. Cohn and his associates for a similar property (7) and discovered that, qualitatively, Fraction IV-3, 4 was active in this respect, as shown by biological and colorimetric tests. By colorimetry it was found that 1 mg. of protein took up a maximum of 0.44 μ g of Fe^{++} . Subfractionation of Fraction IV-3, 4 revealed that the iron-binding protein resides almost completely in a β_1 globulin (Fraction IV-7) (8). This fraction constitutes approximately 3 per cent of the total plasma protein.² Two molecules of either Fe^{++} or Fe^{+++} are bound to one of protein. If the molecular weight of the β_1 globulin is 90,000, the iron content of the iron-protein complex is 0.125 per cent. Studies over a wide range of pH have revealed that at neutral pH the iron is non-dialyzable whereas at pH 5 the iron becomes dialyzable.

Skouge (9) and Waldenström (10) have pointed out that the concentration of serum iron five minutes after the intravenous injection of iron is lower than would be expected on the basis of the quantity injected. This "braking" phenomenon was more pronounced in patients with pernicious anemia in relapse than in normal persons. When the initial serum iron was high, scarcely any rise was noted after the intravenous injection of iron. Furthermore, toxic reactions were observed long before the generally tolerated dose of 10 mg. had been administered. Holmberg and Laurell (11) by means of a colorimetric method in which α - α' -dipyridyl was used, were able to study the capacity of serum to bind iron *in vitro*. They found the "saturation limit" in 10 normal subjects to be 312 μ g per cent (range 264 to 366 μ g). The saturation values corresponded well with the maximum values of approximately 291 μ g per cent obtained by Waldenström (10) after the intravenous injection of 10 mg. of Fe^{++} . These authors explain the "braking effect" observed by Waldenström by assuming that the unbound iron is rapidly eliminated from the circulation. Toxic effects after the intravenous administration of iron were noted only when the saturation limit was exceeded and surplus iron left the blood stream.

Laurell (12) has recently published a comprehensive monograph on the iron-binding component in human plasma. In 100 normal subjects the mean value for the iron-binding capacity of the serum was 315 ± 3.3 μ g per cent. In pregnancy, infectious hepatitis, and acute and chronic blood loss the capacity of the serum to bind iron was found to be increased. In acute and chronic infections, pernicious anemia, hemolytic anemia, cirrhosis of the liver, uremia and malignancy the capacity was found to be diminished. On the basis of these results Laurell has advanced the hypothesis that the body is capable of mobilizing iron from

the depots and, at the same time, can increase the absorption of iron by either lowering the serum iron concentration or by increasing the iron-binding component of the serum. Conversely, by either increasing the serum iron or lowering the iron-binding protein component more iron can be transferred to the depots and the absorption of iron checked.

Studies in this laboratory dealing with the pathogenesis of the anemia of infection have revealed that in the presence of infection a disturbance in iron metabolism occurs (13, 14). There is a pronounced and persistent hypoferremia and when iron is injected intravenously the magnitude of the subsequent increase in plasma iron is less than in normal individuals. The rate of disappearance of iron from plasma following injection has been found to be twice that seen in normal subjects. Neither by repeated intravenous injections nor by the continuous intravenous infusion of iron has it been possible to increase the iron level beyond a certain point. A "braking" mechanism thus operates in the presence of infection which is so powerful that as more iron is given it becomes increasingly difficult to maintain the plasma iron concentration.

In view of these observations it was thought desirable to investigate the role of the iron-binding protein of the serum in the pathogenesis of the anemia of infection. The purpose of this paper is to describe *in vitro* and *in vivo* studies of the iron-binding capacity of serum in normal subjects, in patients with infection, and in animals in which infections were produced experimentally.

METHODS

Preparation of serum. From fasting subjects an amount of venous blood sufficient to provide 8 to 10 ml. of serum was drawn without hemolysis into a syringe and transferred to a centrifuge tube. The blood was allowed to clot, the latter was separated from the glass and the blood was then centrifuged at about 2500 r.p.m. for 15 minutes. The serum was then transferred to a second centrifuge tube and respun to remove all red cells. All determinations were made within three hours after the blood was collected.

Serum iron (SI). For the determination of serum iron the method of Barkan and Walker (15) using the Evelyn photoelectric colorimeter was followed except that twice the quantities recommended by them were used. This required 4 ml. of serum. The results are expressed in μg per cent.

Unsaturated iron-binding capacity (UIBC). For the determination of the unsaturated capacity to unite with

iron, i.e., the binding capacity in addition to that which is already fixed (SI), a modification of the method of Schade and Caroline (7) was used. This method is based on the principle that the iron-protein compound is salmon pink in color (maximum absorption at about 460 m μ) and that the color development is proportional to the amount of iron-protein formed. The serum is therefore titrated with iron until the maximum color develops. The results are expressed in terms of μg of iron bound.

Two ml. of serum and 8 ml. of 0.9 per cent saline are added to each of two colorimeter tubes. Using the Evelyn photoelectric colorimeter and the 490 filter, the blank is set at 100 per cent transmission. The per cent transmission of the other tube is then read. One-tenth ml. of glass-distilled water is added to the blank and

FIG. 1. MEASUREMENT IN HUMAN SERUM OF THE SALMON PINK COLOR DUE TO THE FORMATION OF THE IRON-PROTEIN COMPLEX

Evelyn photoelectric colorimeter. Filter 490.

0.1 ml. of a standard iron solution containing 1 μg of iron is carefully added to the other tube. The tubes are shaken and the per cent transmission is determined four minutes after shaking, again setting the blank at 100. This procedure is repeated until there has been no change in the per cent transmission on three successive readings. The per cent transmission is then plotted against the micrograms of iron added and the saturation point is estimated as illustrated in Figure 1.

The UIBC is calculated by multiplying by 50 the micrograms of iron needed to produce saturation. The values are expressed in μg per cent and represent the micrograms of iron with which 100 ml. of serum are capable of uniting.

Total iron-binding capacity (TIBC). This is calculated by adding the unsaturated iron-binding capacity to the serum iron and is expressed in μg per cent.

Per cent saturation. This is calculated by dividing the serum iron by the total iron-binding capacity.

All glassware must be carefully cleaned with concentrated HCl, washed three times with glass-redistilled water and air dried under cover.

A standard iron solution is prepared by dissolving 0.1 gm. of standard iron wire in 50 ml. of 1:3 nitric acid. The solution is boiled to expel oxides of nitrogen and is then diluted to 1 liter with glass-distilled water. A dilute working standard containing 10 μg of iron per 1 ml. is prepared from this. If properly stored this solution will not change in concentration for several months.

Comment. This method has been found to work equally well when either ferric ammonium sulfate or iron wire is used for the standard solution. The absorption spectrum of the pink iron-protein compound has a rather broad base with a maximum absorption at about 460 $m\mu$. For this reason any filter between 420 and 520 $m\mu$ is suitable but less interference from hemoglobin and bile pigment compounds is encountered in the region of 490 $m\mu$. One to three minutes are required for the development of maximum color after the addition of iron. Fresh, non-lipemic, non-icteric serum must be used. If sufficient serum is not available for a blank this may be dispensed with although the accuracy of the method is thereby slightly reduced. The concentration of the chromogen is low and great care must be taken in making the readings.

Since increments of 1 μg iron are added to 2 ml. of serum and the results are multiplied by 50 in order that they may be expressed in μg per cent the method can be no more accurate than 50 μg per cent. However, triplicate determinations on the same serum have repeatedly given the same result.

EXPERIMENTAL

To determine whether the *in vitro* measurement of the TIBC of the serum is a true measure of the ability of the serum to combine with iron *in vivo*, an amount of iron calculated to exceed the determined TIBC was injected intravenously into each of eight individuals. The iron was administered in the form of a 0.5 per cent solution of iron ascorbate in amounts equivalent to 0.137 mg. Fe^{++} per kilogram of body weight. An initial sample of blood was withdrawn, the iron solution injected in 30 to 60 seconds, and five minutes later a second sample was taken from the other arm. The results are presented in Figure 2. In each instance

FIG. 2. COMPARISON OF THE SERUM IRON LEVEL, THE UNSATURATED PROTEIN AND THE TOTAL IRON-BINDING CAPACITY BEFORE AND AFTER THE INTRAVENOUS INJECTION OF IRON

The horizontal lines represent the expected serum iron values as calculated from the amount of iron administered and the estimated plasma volume. Solid areas represent the serum iron; hatched areas represent the unsaturated capacity to bind iron. The total height of each column represents the total iron-binding capacity. The amount of iron (Fe^{++}) injected is indicated below the various columns.

FIG. 3. RESULTS OF THE REPEATED INTRAVENOUS INJECTION OF IRON AT FIVE-MINUTE INTERVALS IN EACH OF FIVE PATIENTS

The horizontal lines represent the expected serum iron values on the basis of the amount of iron administered and the calculated plasma volume. Solid areas represent the serum iron. Hatched areas represent the unsaturated iron-binding capacity. The total height of each column represents the total iron-binding capacity. The amount of iron (Fe^{++}) injected is indicated below the various columns.

the serum was completely saturated with iron ($\text{UIBC} = 0$) and the measured amount of serum iron corresponded, within the limits of the experimental error, to the previously determined TIBC. A reaction to the injection, manifested by headache, flushing and nausea, was noted within two minutes in each individual. By the time the second specimens were withdrawn the reactions had completely disappeared.

The results of the repeated injection of iron at five-minute intervals into each of five patients are presented in Figure 3. After complete saturation

had been attained the loss of additional iron from the serum within five minutes was approximately 100 per cent. Repeated injections of iron failed to raise the serum iron level above the TIBC. However, when amounts insufficient to reach the saturation limit were given, not all of the iron was retained in the serum, only 50 to 80 per cent being accounted for when plasma volume was calculated as equivalent to 43.1 ml. per kilogram of body weight for males, and 41.5 ml. per kilogram for females. Since it is unlikely that the calculated plasma volume would be in error to the extent of 50 per cent, it is possible that in some instances iron escaped to the tissues even though the serum possessed the capacity to bind it. Toxic reactions were observed only when the TIBC was exceeded.

Determinations of the TIBC have been made in 15 normal males and 15 normal females. The results are presented in Table I. The mean \pm S.D. for the entire group was $359 \pm 30.8 \mu\text{g per cent}$ and the range 306 to 429 $\mu\text{g per cent}$. The values for the female group were somewhat higher than for the male group. In these normal subjects 35 ± 6.4 per cent (26 to 49) of the total iron-binding capacity was saturated.

Studies have been made on 13 patients with chronic infections and six patients with iron deficiency anemia. The results are presented in Figure 4. In chronic infections, in each instance, the TIBC as well as the serum iron was reduced below the lower limits of normal. The reduction in serum iron was proportionately greater than the decrease in TIBC, the per cent saturation being

TABLE I
Summary of the normal data

Group	No. determ.	UIBC	SI	TIBC	% Sat.
Males	15	220 ± 24.7 (180-250)	127 ± 29.2 (79-196)	347 ± 26.1 (306-396)	36 ± 7.78 (24-49)
Females	15	248 ± 34.4 (200-300)	123 ± 19.2 (101-164)	371 ± 35.9 (316-429)	33 ± 4.92 (26-42)
Total	30	234 ± 29.4 (180-300)	125 ± 24.2 (79-196)	359 ± 30.8 (306-429)	35 ± 6.4 (26-49)

UIBC refers to unsaturated iron-binding capacity in $\mu\text{g per cent}$.

SI refers to serum iron in $\mu\text{g per cent}$.

TIBC refers to total iron-binding capacity in $\mu\text{g per cent}$.

% Sat. (per cent saturation) = $\frac{\text{SI}}{\text{TIBC}} \times 100$

Figures represent mean \pm standard deviation.

Figures in parenthesis represent range.

between 7 and 26 per cent in all but two patients. In these two cases the decrease in serum iron was proportional to the decrease in TIBC and the per cent saturation remained within the limits of normal (26 to 49 per cent). In contrast, in the patients with iron deficiency anemia the TIBC was increased above 450 μg per cent. Since the serum iron is very low in iron deficiency, the per cent saturation was below 10 in all.

The change in TIBC in relation to the rise in serum iron which occurs during recovery from infections was followed in six patients. The results are presented in Figures 5-9, and 12. These studies showed that in infections the total iron-binding capacity per 100 ml. serum increased, as did the serum iron, following successful treatment and anemia, when present, tended to disappear (Figures 5-7). The per cent saturation of the iron-binding protein with iron did not change greatly.

In a more chronic infection (Figure 8) the changes following streptomycin therapy were very gradual but in another case (lung abscess, Figure 9) the improvement following thoracotomy was more striking.

To determine if the intravenous administration of metal-combining globulin (Fraction IV-7) together with iron might increase the TIBC to normal and thereby prevent the rapid disappearance of iron from the serum which occurs in the presence of infection, these substances were given to two patients with chronic infections. In each patient the rate of disappearance of iron from the serum after its intravenous injection was measured two days prior to the administration of the metal-combining globulin, sample measurements being taken at 0, five min., one, three, five, seven, 24, 48 and 96 hours after the injection. The amount of globulin to be administered was then added to 500

FIG. 4. THE TOTAL IRON-BINDING CAPACITY OF THE SERUM IN 13 CASES OF ANEMIA ASSOCIATED WITH INFECTION AS COMPARED WITH THE NORMAL AND SIX CASES OF IRON DEFICIENCY ANEMIA

Solid areas represent serum iron. Hatched areas represent the unsaturated iron-binding capacity. The total height of each column represents the total iron-binding capacity of the serum. The figures above the columns represent the per cent saturation (SI/TIBC).

FIG. 5. SHOWING THE SHARP RISE IN THE IRON-BINDING CAPACITY OF THE SERUM (TIBC) IN A PATIENT (I. C.) RECOVERING FROM LOBAR PNEUMONIA, THE INCREASE IN SERUM IRON (SI) AND THE DISAPPEARANCE OF ANEMIA (REPRESENTED BY THE VOLUME OF PACKED RED CELLS (Ht.))

UIBC refers to unsaturated iron-binding capacity. Per cent saturation is the ratio of SI to TIBC.

FIG. 10. THE EFFECT OF THE INJECTION OF 5 GM. OF METAL-COMBINING GLOBULIN (FRACTION IV-7) ON THE TOTAL IRON-BINDING CAPACITY OF THE SERUM IN A PATIENT (J. A.) WITH TUBERCULOSIS

For symbols see Figure 2. The serum iron rose to a somewhat higher level following the injection of iron than before globulin was given and the subsequent decrease in serum iron was slower but after 24 hours the level was the same as originally.

FIG. 11. THE EFFECT OF THE INJECTION OF 6 GM. OF METAL-COMBINING GLOBULIN (FRACTION IV-7) ON THE TOTAL IRON-BINDING CAPACITY OF THE SERUM IN A PATIENT (J. K.) WITH CHRONIC EMPYEMA

Although the TIBC increased to a higher level than in patient J. A. (Figure 10) this did not succeed in maintaining an elevated serum iron level. For symbols see Figure 2.

ml. of saline and given over a one-hour period. Five minutes after this was completed a sample of blood was withdrawn for analysis and the same quantity of iron injected (0.137 mg. per kilogram body weight) as had been given two days previously. The results are presented in Figures 10 and 11 and illustrate several points of interest. The administration of the metal-combining globulin increased the TIBC to within normal limits in both patients. The iron-binding capacity of the protein injected was $0.72 \mu\text{g Fe}^{++}$ per milligram of protein. Therefore, all of the material injected could be accounted for in the serum on the basis of the calculated plasma volume. There was no evidence of inactivation of the binding capacity within two to three hours. The levels of serum iron reached when metal-combining globulin was given in addition to iron were somewhat higher in one case

and much greater in the second case, as compared with those obtained when iron was injected alone. The rate of disappearance of iron from the serum was not diminished, however. In both individuals the serum iron returned to its previously low level within seven hours in spite of the increased TIBC. The TIBC returned to its previously low level in 48 hours in one patient (Figure 10) and in 96 hours in the other (Figure 11). The temporary restoration of the TIBC to normal in these cases apparently did not result in a detectable mobilization of iron from the tissues to the blood.

It is of interest to note that while the intravenous injection of metal-combining globulin together with iron was not followed by a significant change in the serum iron, thoracotomy with relief of the underlying disorder was associated with a steady increase in total iron-binding capacity, a gradual

FIG. 12. TO COMPARE THE VERY TRANSIENT RISE IN THE TOTAL IRON-BINDING CAPACITY AND SERUM IRON IN A PATIENT (J. K.) FOLLOWING THE INJECTION OF 6 GM. OF METAL-COMBINING GLOBULIN (FRACTION IV-7) AND 8.4 MG. Fe^{++} AS IRON ASCORBATE WITH THE STEADY RISE FOLLOWING THORACOTOMY WITH RELIEF OF THE EMPYEMA

The serum iron also rose. The saturation of the iron-binding protein with the iron increased and the anemia disappeared. (Same patient as in Figure 11.) For symbols see Figure 5.

rise in serum iron, increased saturation of the iron-binding protein with iron and relief of the anemia (Figure 12).

Since it has been demonstrated that patients during febrile paroxysms following the administration of typhoid vaccine rapidly develop hypoferrremia (16) the TIBC was followed in such a patient during two paroxysms of fever (Figure 13). No significant change took place even though hypoferrremia developed.

In an attempt to determine the rapidity with which a reduction in TIBC takes place in the presence of inflammation, an abscess was produced in a dog by the intramuscular injection of staphylococci (Figure 14). Twenty-four hours after the production of the infection the SI had fallen from 130 μg per cent to 35 μg per cent. There was also a reduction in the TIBC at this time but maximum reduction did not take place until the third day at

which the SI had returned to normal. Two other dogs received repeated injections of turpentine (Figures 15 and 16). In each animal, 24 hours after an injection hypoferrremia developed and a fall in the TIBC occurred. The decrease in serum iron was always greater than the decrease in TIBC and the per cent saturation thus decreased. In each instance the maximum decrease in TIBC took place after maximum hypoferrremia had developed with the result that as the SI rose the per cent saturation increased. Following three of the six injections the serum became 100 per cent saturated during the rebound in iron content.

DISCUSSION

In 13 patients with chronic infections, in two dogs in which sterile abscesses were produced and in a single dog in which an acute infection was introduced, the total iron-binding capacity (TIBC) of the serum was reduced as compared with the normal, as was the serum iron. The reduction in the latter was proportionately greater, with the result that the per cent saturation with iron was decreased. The intravenous administration of the iron-binding protein to two patients with chronic infections increased the TIBC of the serum to nearly normal values for a period of approximately 24 hours without diminishing the rate of disappearance of iron from the serum. Furthermore, in a patient given typhoid vaccine hypoferrremia developed without a significant change in the TIBC of the serum. Again, in the dogs given injections of turpentine or staphylococci hypoferrremia preceded the maximum fall in TIBC; in both dogs and patients, even though the TIBC was diminished, the per cent saturation of the protein with iron was also reduced due to the greater fall in serum iron; and finally, there appeared to be no correlation between the degree of hypoferrremia and anemia and the degree of reduction of the TIBC. From these observations it would appear that some factor other than a reduction in the iron-binding protein is responsible for the hypoferrremia associated with infection. Since in conditions in which the demands of the body for iron are increased, namely, iron deficiency and pregnancy, there is an increase in the TIBC of the serum, and since in those disorders in which the demand of the body for iron is decreased such as pernicious anemia in relapse (12), there is a decrease in the TIBC,

FIG. 13. THE EFFECT OF FEVER INDUCED BY THE INJECTION OF TYPHOID VACCINE ON THE TOTAL IRON-BINDING CAPACITY AND THE SERUM IRON

For symbols see Figure 5.

the question might be asked: Does the reduction in TIBC in infection reflect an attempt to reduce the intake of iron? With the information now available this question cannot be answered.

In most of the patients with infections the TIBC was reduced to about 43 per cent of the normal mean and in one patient the value was reduced 78 per cent. The total serum proteins were in general within the normal range although occasionally they were in the lower limits of normal. Thus the reduction in the iron-binding protein was out of proportion to the general reduction in serum proteins.

From our observations it would appear that after the intravenous administration of iron the height of the rise is limited by the capacity of the serum to bind iron. When the TIBC of the serum is exceeded the unbound iron rapidly leaves the blood stream and toxic symptoms develop. Since the TIBC is reduced in infections an explanation is now available for our previous observation that

the initial five-minute rise was not as great in patients with infections as in normal subjects (13).

Goetsch, Moore and Minnich (16) have observed serum iron values from 0.622 to 3.86 mg. per cent in patients following the intravenous injection of massive doses of iron (from 0.608 to 1.32 gm. as colloidal hydroxide and colloidal ferric oxide). Moore, Arrowsmith, Welch, and Minnich (17) observed serum iron values in dogs as high as 1.60 mg. per cent after the intravenous administration of 1 mg. Fe^{++} per kilogram of body weight. These experiments differ from ours in that much larger doses were used. It may be that with the administration of doses such as Moore and his associates gave, the iron combines with other proteins.

As far as our own observations are concerned, the failure of the serum iron to rise above the level of the TIBC when 0.137 mg. Fe^{++} per kilogram were given intravenously, appeared to be so consistent that we would suggest that the most

the method of determining the TIBC is by measuring the serum iron five minutes after the injection of a supersaturating amount of iron.

It may be noted in passing that, since the toxicity of injected iron seems to be dependent upon the presence of unbound iron in the serum, it is unlikely that any one particular iron compound, other than iron in combination with protein or colloidal iron, can be less toxic than another.

SUMMARY

1. The total iron-binding capacity (TIBC) of the serum was measured in 30 normal individuals. The mean \pm S.D. was 359 ± 30.8 μ g per cent. The saturation of the iron-binding protein with iron was found to be 35 ± 6.4 per cent.

2. The total iron-binding capacity of the serum was measured in 13 patients with chronic infection, in two dogs in which sterile abscesses were produced, and in a single dog given an acute in-

fection. The TIBC was found to be significantly reduced in each instance. The reduction in the serum iron was proportionately greater than the reduction in iron-binding capacity with the result that the per cent saturation was lowered.

3. The total iron-binding capacity of the serum was also measured in six patients with iron deficiency and found to be increased. The per cent saturation of the iron-binding component was less than 10 in each instance.

4. The administration of metal-combining globulin (Fraction IV-7) to two patients with chronic infections resulted in a temporary increase to normal in the total iron-binding capacity of the serum. Following the administration of this fraction the intravenous injection of iron resulted in a greater initial five-minute rise in the serum iron than previously but the rate of disappearance of the iron from the serum was not significantly affected. Furthermore, the temporary increase in

the iron-binding capacity of the serum did not result in a detectable mobilization of iron into the blood.

5. The administration of typhoid vaccine to a patient produced a transient hypoferremia without a significant change in the iron-binding capacity of the serum.

6. These observations would indicate that the hypoferremia which accompanies infections is not the result of a reduction in the iron-binding capacity of the serum but is dependent upon some other factor.

7. The observations of Holmberg and of Laurell that the "braking" mechanism described by Waldenström is attributable to the fact that iron, in excess of that which can be bound, rapidly leaves the blood stream, and their conclusion that the intravenous administration of iron in excess of the amount which can be bound produces toxic symptoms, have been confirmed.

ACKNOWLEDGMENT

For the supply of Fraction IV-7 as well as cryo-metal-combining globulin, we are indebted to J. Cohn, Harvard Medical School, Boston, Mass.

POTASSIUM DEFICIENCY AND THE ROLE OF THE KIDNEY IN ITS PRODUCTION^{1,2}

By ROBERT TARAIL³ AND J. RUSSELL ELKINTON⁴

(From the Department of Internal Medicine, Yale University School of Medicine, New Haven)

(Received for publication June 24, 1948)

It has been recognized that a depression of the concentration of potassium in serum may reflect a concomitant deficiency of potassium in the cells of the body (1). Low concentrations of potassium in serum and diminished potassium contents of skeletal muscle have been reported in experimental animals maintained on diets deficient in potassium (2) and in animals treated with large doses of desoxycorticosterone (3). Depressions of the concentration of potassium in serum have been observed clinically in patients receiving desoxycorticosterone (4), in familial periodic paralysis (5, 6), in diabetic acidosis (7, 8), in intestinal obstruction (9), and in diarrhea (10). In some of these conditions deficit of cellular potassium has been indicated by negative balances of potassium when the intake of potassium was low and retention of potassium when the ion was administered (10-13). However, significant alterations in the cellular content of potassium may occur without much change in the amount and concentration of potassium in the extracellular fluid and serum (10, 14). Levels of serum potassium therefore, may, but do not necessarily, reflect the state of depletion or repletion of cellular potassium.

The study reported here was undertaken in an attempt to elucidate some of the clinical problems of potassium deficiency in adult patients. These problems include the relation of the concentration of potassium in serum to cellular deficiency of the ion, the extent of such cellular deficiencies and their relation to retention of administered potassium, and the physiological abnormalities by which such deficits are produced.

EXPERIMENTAL MATERIAL AND PROCEDURE

Six adult patients on the medical and surgical services of the New Haven Hospital were studied. Of these, five were suffering from conditions involving extensive losses of fluids from the gastrointestinal tract, and the sixth had a cerebral vascular disturbance with quadriplegia. All the patients were being sustained wholly or in part by parenteral fluids with minimal amounts of potassium. Four of the patients with gastrointestinal fluid loss had abnormally low concentrations of potassium in serum.

In all patients exchanges of chloride, sodium, potassium and nitrogen were measured during a series of periods of 24 hours or longer. In five of the patients these measurements were made in one or more preliminary periods during which a negligible amount of potassium was given. These were followed by periods of potassium administration. In Case 1, A. M., potassium was given in the initial period. In five cases the potassium was given parenterally as K_2HPO_4 and KH_2PO_4 in molar ratio of 3.55 to 1 to yield a pH of 7.35; in the sixth case it was given as KCl. These potassium salts, added to the other intravenous fluids in concentrations up to 70 m.eq. per liter, were given slowly at a rate not in excess of 20 m.eq. per hour. The amount of potassium given by the intravenous route varied from 29 to 167 m.eq. per day. Water and sodium chloride were administered according to the clinician's opinion of the various requirements of the moment; before potassium therapy was instituted, two of the patients were maintained on intakes high in sodium (J. L., E. R.), and four on intakes low in sodium in varying degrees. All of the patients were given carbohydrate and casein hydrolysate during most of the periods. Clinical diagnoses are appended to Table I.

Two normal control subjects were maintained for three successive 24-hour periods on a liquid diet of milk fortified with "Dextri-Maltose." This diet was isocaloric with the usual daily intake of the subjects and kept them approximately in nitrogen equilibrium. On the second of the three days, 10 grams of KCl were added to the diet to ascertain whether retention of potassium could be induced under these circumstances in a normal subject during a 24-hour period or longer.

One normal control subject was also given an isocaloric diet low in potassium for two 24-hour periods. The diet consisted of a solution of casein, lactose, butter and sodium chloride. The experiment was designed to determine the minimal rate of renal excretion of potas-

* Determined directly or calculated from the concentration of serum protein.

† Calculated by changes in chloride balance forward and backward from an assumed extracellular volume (designated by parentheses).

‡ The balance of protein is corrected for change in NPN throughout an assumed volume of body water.

§ Estimated from Sherman's tables (17).

** Assumed.

†† Cumulative changes during potassium administration. Except where indicated balance data are expressed per individual period rather than cumulatively. Time as designated by date indicates end of period at which time serum analyses were made and balances for the period determined.

sium in a subject in nitrogen equilibrium and not initially depleted of potassium.

METHODS

The amounts of potassium and sodium in serum, urine, and other body fluids were measured with the flame photometer (15). The other chemical methods which were used, and the methods of calculation of the derived data, have been previously reported (14, 16). In the present study the concentration of potassium in extracellular fluid was assumed to be the same as that in serum because of the uncertainty concerning the proportion of the latter which is non-diffusible. Any error in this assumption would have little effect on the calculated transfers of intracellular potassium. In order to differentiate at least to some extent between transfers of potassium which are associated with cellular anabolism or catabolism and those which are not, a relationship of potassium to nitrogen

must be assumed. In the former studies just cited a ratio was used of potassium to nitrogen of 2.4 m.eq. to 1 gram; the same ratio has been employed in the present calculations to determine the movements of potassium in "excess" of nitrogen. Use of the K:N ratio of 3:1 as advocated by Darrow (10) and which probably represents the upper limit of this ratio, would increase the magnitude of the change in cell potassium associated with nitrogen by 20 per cent, but would not significantly alter the direction of change of excess cell potassium or the conclusions based thereon.

RESULTS

The analytical and derived data are presented in Tables I and II and in Figures 1 to 6.

The patients retained a significant portion of administered potassium in the cellular phase in ex-

FIG. 1. EXCHANGES OF POTASSIUM AND NITROGEN IN A PATIENT TREATED WITH POTASSIUM PHOSPHATE

Two periods are shown of potassium administration to a patient (A. M., Case 1) with a duodeno-biliary external fistula who received nothing by mouth for 34 days. On Days 1 to 7 inclusive, potassium phosphate was given by vein, on Days 15, 16, and 19 by enterostomy.

Potassium retention in the cellular phase was maximal during the first three days; little was retained thereafter. When potassium was stopped during Days 17 and 18 urinary excretion of potassium persisted. Except for one 24-hour period, more potassium was invariably excreted in urine than in gastrointestinal fluid.

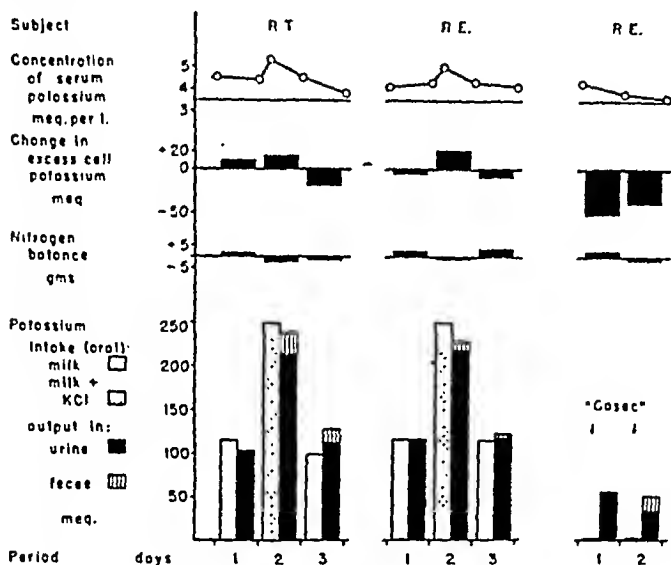

FIG. 2. EXCHANGES OF POTASSIUM IN TWO CONTROL NORMAL SUBJECTS ON HIGH AND LOW INTAKES OF THE ION

In all three experiments the subjects were on isocaloric diets. In the first two experiments the moderate oral intake of potassium in milk was supplemented on Day 2 with KCl. No significant amounts of potassium were retained. In the third experiment, despite the low intake, potassium continued to be excreted in the urine and a cellular deficit was initiated.

ess of nitrogen. As the control subjects did not, this retention presumably indicates a pre-existing cellular deficit of the ion. The magnitude of the deficit was not defined by the extent of retention in each patient, however, since only in Case 1, A. M., was potassium administered for a sufficient length of time to demonstrate that the patient's cells were approaching saturation (Figure 1); the other patients were still retaining potassium at the end of the study. The amount of potassium so retained ranged between 73 and 232 m.eq., or 1.2 to 4.6 m.eq. per kilogram of body weight (Table II). The upper limit of this range would be increased to 283 m.eq., or 7.0 m.eq. per kilogram, if the last two days of Case 2, E. R., are included when the intake of potassium in food was calculated from Sherman's tables (17). The two normal subjects who were given somewhat larger quantities of potassium, retained 0.1 m. eq. per kilogram each over the three 24-hour periods; essentially all of the potassium given was excreted (Table II, Figure 2).

The cellular deficits of potassium as demonstrated by retention of the ion were usually, but not always, associated with a low concentration of

serum potassium; when the concentration of potassium in the serum was low a cellular deficit was always present (Figure 3, [a]). When the cellular content of potassium was increased, both the serum concentration and the absolute amount of extracellular potassium tended to rise; but considerable alteration occurred in the former fraction of potassium with relatively minor changes in the latter two values (Figure 3, [b and c]).

The major factor in the development of deficits of potassium in these patients appeared to be the continued excretion of potassium by the kidney during times of restricted ingestion of the ion. Since these patients were not studied quantitatively from the time of onset of their disease, the data do not contain complete evidence concerning the mode of origin of the potassium deficits. Loss of potassium by vomiting and diarrhea must have been a contributory factor. In Cases 1 to 5 fluid had been lost steadily from stomach or upper small intestine for periods of four days to three months, immediately preceding the studies. Direct analyses of samples of such fluids in four of these cases revealed potassium concentrations one to six times as high as those of normal serum, and losses of as

much as 41 m.eq. per day (Case 1, A. M.). As the potassium intake of vomiting patients is low, a negative balance may ensue and reach significant proportions over a period of days.

However, during the periods studied, with one exception, more potassium was lost in urine than in gastrointestinal fluid (Table I). In both the patients and the normal subjects the capacity of the kidneys to conserve the ion was limited. In Figure 4 the line which defines the relation between the rate of administration and the rate of excretion of potassium in the normal subjects, does not pass through the origin but intersects the abscissa at approximately 40 m.eq. per day. Some of the patients on low intakes excreted less potassium, but the ion never disappeared from the urine. In three of these patients (A. M., R. W., M. McK.)

who were in nitrogen equilibrium the conditions were optimal for renal conservation of potassium. Yet the rates of potassium excretion in these patients were 28, 27, and 5.5 m.eq. per day, and the lowest concentration ratio of urine to serum (U/P) was 1.0. Under these conditions and in these patients, there was no direct evidence of active tubular reabsorption of potassium against a concentration gradient.

The height of the concentration of potassium in serum was less well correlated with the rate of excretion in the patients than in the normal subjects (Figure 5, Tables I and II). In some of the former, more potassium appeared in the urine when the serum concentration was low than when it was at higher levels; in the latter, slight increases in the serum levels were associated with

FIG. 3. COMPARISON OF CHANGES IN EXCESS CELL POTASSIUM WITH (A) THE INITIAL LEVEL AND (B) THE CHANGES IN CONCENTRATION OF SERUM POTASSIUM, AND (C) WITH THE CHANGES IN AMOUNT OF EXTRACELLULAR POTASSIUM

The control subjects are represented by crosses, the patients by circles. Open circles represent the total changes for consecutive periods when the intake of potassium was low, closed or partially closed circles represent similar periods when the intake was high. The half-solid circle is the probable summation of two periods of high potassium intake (quarter-solid circles) in R.W., Case 4.

Retention of cellular potassium is roughly correlated with an initial low level of serum potassium (a), with a rise in serum potassium concentration (b), and with small increases in the amount of extracellular potassium (c).

FIG. 4. RELATION OF THE DAILY EXCRETION OF POTASSIUM IN URINE TO THE DAILY INTAKE OF POTASSIUM

Data are for 24-hour periods, crosses represent periods of low (+) and high (x) intake of potassium in the normal subjects. Open and solid circles represent similar periods, respectively, in the patients.

Potassium excretion varied directly with the intake of the ion in the normal subjects but not in the patients. In both groups, the excretion of potassium persisted when the intake was negligible.

large increases in the renal excretion of the ion. The concentration of serum potassium was measured at intervals of 24 hours; levels at intermediate points closer to the actual time of potassium administration were probably higher, at least in the normal subjects. Failure of the serum concentra-

FIG. 5. RELATION OF THE DAILY EXCRETION OF POTASSIUM IN URINE TO THE AVERAGE CONCENTRATION OF POTASSIUM IN SERUM

Symbols are the same as in Figure 4. In the normal subjects, slight increases in serum concentration were associated with large increases in the rate of excretion of potassium. This relationship did not hold in the patients.

tion to rise to comparable intermediate levels might explain the failure of the patients to excrete as much potassium as did the controls. In the former the amount of potassium excreted in the urine bore no relation to the amount of potassium given (Figure 4). In four of the patients actually less potassium was excreted during periods of high intake than during those of low intake. Unfortunately our data cannot define completely the role of the serum potassium level in this phenomenon, but presumably the primary cause for the failure of the patients to excrete administered potassium was the avidity of the cells of other tissues for the ion.

FIG. 6. COMPARISON OF CHANGES IN EXCESS CELL POTASSIUM AND IN CELL SODIUM

Symbols are the same as in Figure 3, except that the summation of periods in Case 4, R.W., is omitted. An inverse relationship is present in only a few of the periods.

Disturbances in the distribution of other electrolytes could not be causally related to the potassium deficiencies in our patients. There was no consistent relationship between the concentrations in the serum of sodium or chloride and those of potassium (Table II). An inverse relationship between changes in cell sodium and changes in cell potassium was present in only a few of the patients (Figure 6). The CO_2 content of serum was abnormally high at some stage in the course

of these studies in four of the six patients, but only in Case 1 was it clearly unrelated to the intravenous infusion of alkali or to a possible primary CO_2 excess (Table II). The administration and retention of potassium did not appear to alter significantly the nitrogen balance. Only in two cases (Cases 3 and 5) did the latter become less negative or more positive when potassium was given while the nitrogen intake was maintained at the same level (Table I).

Electrocardiographic and clinical findings in these patients were surprisingly non-specific with respect to potassium deficiency. In the patients with low concentrations of serum potassium, electrocardiographic abnormalities, *e.g.*, depression of the T waves, were noted which were similar to those previously reported (18, 19). There was no precise correlation between the level of serum potassium and the degree of electrocardiographic disturbance. During the course of infusions of potassium these abnormalities sometimes receded but no cardiotoxic effects supervened. No definite symptoms or physical signs of neuromuscular disturbance, respiratory embarrassment, or specific cardiac abnormality were observed, despite the fact that four of the patients had concentrations of serum potassium in the range of those reported in familial periodic paralysis (5) and in other patients in whom paralytic phenomena were attributed to hypokalemia (7, 20, 21). No detrimental effects of potassium administration were seen with the following exceptions: in Case 1 more fluid was lost through the rectum when potassium phosphate was added to the fluid given through the enterostomy, and diarrhea occurred in one of the normal subjects following the ingestion of potassium chloride. Otherwise, the patients tolerated the potassium therapy well.

DISCUSSION

Limits and sources of error. The magnitude of changes observed in these studies greatly exceeded any possible sources of errors in chemical determinations. This was also true with respect to the collection of specimens despite the fact that the patients were studied on the open ward. Electrolyte losses in sweat were not measured. As the patients were not sweating profusely, this neglect as far as potassium is concerned would be of minor importance (22); in the case of chloride and so-

dium, the error might be greater, but probably would not significantly alter results.

The derived data were calculated on the basis of certain assumptions which are open to question. Changes in extracellular potassium were estimated from alterations in the chloride space. Admittedly some chloride is intracellular but its magnitude is small. In addition the extracellular potassium is a relatively minor fraction of total body potassium. The questionable validity of equating the chloride space with the extracellular fluid, therefore, does not invalidate the derived data on exchanges of cellular potassium. But the relatively large extracellular component of sodium does mean that the estimated changes in cellular sodium are only rough approximations.

A relationship of potassium to nitrogen has been assumed in order to calculate which transfers of cellular potassium were due to tissue anabolism or catabolism, and which were occurring in intact tissue cells. Such K:N ratios as have been used for this purpose have been derived either from tissue (skeletal muscle) analyses or from the excretion of these substances by fasting subjects (16, 23). It is possible that this relationship may vary widely in other circumstances (24, 25, 26). But the K:N ratio was used as the only available yardstick to permit at least some differentiation between these two types of transfers of cellular potassium. In any case the uncorrected change in cellular potassium was in the same direction as significant changes in excess potassium in all the subjects studied, and the correction for potassium associated with nitrogen was small in most instances.

Relation of retention of potassium to deficit of the ion. The two control studies indicate that extra potassium given to a normal subject is not retained. Similar evidence has been found in previous investigations for both shorter and longer periods of time (27 to 30). Since the potassium was administered to both the patients and the control subjects in comparable amounts, and over a comparable period of time, there appears to be some justification in equating retention of the ion with a pre-existing deficit.

The patients retained 1.2 to 7.0 m.eq. of excess cell potassium per kilogram. Darrow's infants with diarrhea retained 5.8 to 17.3 m.eq. per kilogram (10). However, the estimation of a deficit by the retention of an administered substance re-

quires saturation of the subject; *i.e.*, it must be given until no more is taken up by the cells. Since only one patient, Case 1, (A. M.), was so saturated, the positive balances of potassium exhibited by the other patients probably did not measure the full extent of their potassium deficits.

Mechanism of potassium depletion. During the periods of study our patients lost smaller quantities of potassium in gastrointestinal fluids than in urine, although larger quantities may have been lost via the gastrointestinal tract during the periods preceding the studies. Undoubtedly this latter route of loss may be of greater importance in many cases of diarrhea (10), steatorrhea (12), and vomiting (9). But in the cases presented here, a low intake of potassium in conjunction with the continued excretion of the ion in the urine was an important, if not the principal, factor in producing the cellular deficit.

Excretion of potassium in excess of nitrogen and negative balances of potassium are familiar phenomena in a variety of physiological disturbances. These have been observed in diverse groups of patients maintained on the usual varieties of parenteral fluids and may be accelerated during post-operative periods as part of an injury reaction (31 to 34); they occur during starvation (23) and dehydration (16). The nature of these disturbances suggests that processes of cellular metabolism play an important role in determining the total exchanges of potassium. Our data, however, emphasize the importance of the renal excretion of the ion.

The continued renal excretion of potassium by our patients during periods of low potassium intake does not indicate abnormal renal function, but rather normal function of the kidneys under abnormal circumstances. With one possible exception there was no evidence that any of these patients had diseased kidneys. Their rates of potassium excretion were quite comparable with that of the control subject (R. E.) on a low potassium diet. Furthermore, most patients with severe renal disease have a lower rather than a higher rate of excretion of the ion (35). It is necessary, therefore, to consider the ways in which the abnormal conditions influence the excretion of potassium by the normal kidney.

Winkler and others have demonstrated that under normal conditions increases in the intake of

potassium and in its concentration in serum are associated with increases in the rate of excretion of potassium (27, 28, 36). These findings are confirmed in the control experiments reported here in that large increments of potassium in the urine occurred with slight rises in the serum concentrations. Intermediate analyses of the serum level might have revealed higher concentrations. In the patients during periods of cellular depletion of the ion no positive correlation was apparent between intake of potassium or its concentrations in serum and the daily output of potassium. Rapid uptake of potassium by the cells may have prevented comparable intermediate rises in serum concentrations thus explaining the failure of the kidney to excrete it. But such a simple explanation can hardly account for the fact that in some instances the rate of excretion of potassium was actually lower during periods of administration when the average serum level was normal, than during periods when intake and serum concentration were low. The administration of potassium appeared to shift the equilibria of potassium transfers in the various phases of body fluid from the direction of excretion in the kidneys to movement into tissue cells.

Potassium has been regarded as a "threshold" substance (37). Concentrations of urine potassium below 4 m.eq. per liter have been recorded during diuresis and potassium depletion (11, 28, 38, 39). Concomitant serum concentrations in one study were not greater than those in urine, and in the other studies no concomitant serum concentrations of potassium were reported. In our patients the concentration of potassium was never lower in urine than in serum. Considering renal tubular function as a whole and assuming that the tubular cells are surrounded by the usual type of extracellular fluid, no evidence has been found that potassium can be reabsorbed against a concentration gradient. This does not exclude the possibility that such reabsorption may occur in a given portion of the renal tubule.

Relation of transfers of cellular potassium to those of other ions. Aside from the renal excretion of potassium, it is pertinent to inquire into the relation of transfers of cellular potassium to the exchanges of other extracellular and intracellular ions.

The data confirm previous studies in this laboratory and elsewhere (14) in showing that large

amounts of potassium may enter or leave the intracellular fluid with relatively small increments or decrements of the extracellular fraction of the ion. Some changes in concentration of extracellular potassium may take place. The data show that an abnormally low concentration was always associated with a cellular deficit of the ion. But the converse was not true; one patient, Case 4, (R. W.), had a normal concentration, and one, Case 2, (E. R.), had an elevated concentration of potassium in serum. This is consistent with other investigations in which the evidence suggests that cellular deficiency of potassium may co-exist with normal or elevated concentrations of the ion in the extracellular phase (10, 33, 34). As many patients are suffering from salt loss, dehydration, peripheral vascular collapse and oliguria, it has been suggested that this phenomenon is the result of impairment of renal function. This did not appear to be the fact in Case 4, R. W., but might well explain the high serum concentration observed in Case 2, E. R. This apparent paradox must be kept in mind during any attempt to assess the potassium requirement of the patient.

Under certain circumstances a close relationship has been noted between potassium depletion and alkalosis due to excess of bicarbonate in the extracellular fluid. In four of our six patients the concentration of serum bicarbonate was elevated to some extent before potassium therapy and fell to within normal limits after administration of the ion. Darrow postulated that such a relationship holds only under certain conditions, viz., deficit of only one ion (e.g. potassium), and attainment of a state of equilibrium by adequate renal function (40). All of our cases were studied for periods of 24 hours or longer during which renal function was adequate, but electrolyte deficits were not restricted to only one ion. It is interesting, therefore, that our data fit in as well as they do with Darrow's findings.

One other observation is noteworthy: the elevated serum bicarbonate concentration in Case 1, A. M., did not return to normal after the deficit of cell potassium had been corrected during four days of treatment, but did return to normal three days later when the equivalent amount of sodium had been discharged from the cells. If the change in serum bicarbonate is necessarily related to transfers of either of these cellular cations, this temporal

sequence suggests that it is to the exit of sodium from the cell rather than to the entry of potassium. Such a time lag between the two transfers has been noted in experimental animals by Conway and Hingerty (41). Had the other patients in our series been "saturated" and studied for a longer period of time, reciprocal movements of cellular sodium might have been observed more frequently.

Administration of large quantities of sodium without concomitant use of potassium has also been said to predispose to potassium depletion (42). In four of the patients the intake of sodium, prior to potassium therapy, was low. In none of the cases was depletion of cellular potassium consistently correlated with changes in the concentration of extracellular sodium. It is difficult, therefore, to assess the specific role of sodium therapy, or that of alkalosis, in the cases presented, but certainly deficit of potassium can occur in the absence of either.

Within the limits of the relatively large error of the calculation, a reciprocal relationship between changes in cell sodium and cell potassium was found only occasionally in our studies. Such a relationship appeared to be present in some instances. These results are in agreement with those of Darrow who demonstrated a reciprocal relationship in only three of the six infants with diarrhea whom he treated with potassium (10), and with previous studies in this department (16).

Clinical implications. The subjects of this investigation were probably representative of a large group of patients seen in ordinary hospital practice. All of the patients were maintained on parenteral fluids and were unable to eat. In addition most of them had lost gastrointestinal fluids to some degree. The incidence of unrecognized deficiency of potassium in such patients must be very great.

The diagnosis of potassium deficiency is not simple, as specific signs and symptoms are probably the exception rather than the rule. The diagnosis depends chiefly on recognition of the conditions under which it may develop. The most important of these appears to be a low potassium intake in association with normal renal function. An abnormally low concentration of potassium in serum is strongly suggestive of cellular deficit; a normal or high serum concentration does not ex-

clude it. The most practical proof of the diagnosis at present is demonstration of cellular retention of administered potassium. Other methods include chemical analyses of tissue and possible measurement of total exchangeable potassium by means of the radioactive isotope, K^{42} (43).

Complete elaboration of the contraindications to potassium therapy awaits more extensive clinical experience. In the meantime it is certain that the most important contraindication is inadequate renal function due to any cause (35). Oliguria or anuria caused by intrinsic disease or extrinsic factors are absolute contraindications. As patients who are likely to have potassium deficiency are also likely to be suffering from peripheral vascular collapse, due at least in part to dehydration and sodium depletion, potassium therapy should be deferred until appropriate treatment for these conditions has been instituted. Adrenal cortical insufficiency is a contraindication unless this condition is overtreated with desoxycorticosterone or cortical extract. The limited experience with potassium therapy in patients with organic cardiac disease and associated potassium deficit, permits no comment concerning possible cardiac contraindications (44).

It is not known whether an excessive amount of potassium in the intracellular fluid is deleterious to the organism. But accumulation of potassium in the extracellular fluid is dangerous if it results in an elevation of concentration. The cardiotoxic effects of such an elevation are well known (45 to 49), and may be fatal; other possible toxic effects are less well understood (46). A high concentration of potassium in serum, therefore, contraindicates potassium therapy even though the cells may be depleted of the ion. Evidence has been advanced of increased hazard of potassium administration under certain circumstances when the concentration of serum calcium is low (50).

No arbitrary parenteral dose of potassium can be prescribed. Darrow has estimated that 3.5 m.eq. per kilogram per day of potassium can be administered safely in a period exceeding four to eight hours (51). The subjects of this study received up to 3.7 m.eq. per kilogram per day. The rate of intravenous infusion of the potassium was carefully controlled and not allowed to exceed 20 m.eq. per hour. The concentration of the potassium in the infusion fluids was as high as 70 m.eq. per liter, a concentration which is double that rec-

ommended by Darrow (51). Under these conditions no untoward effects were observed.

No evidence is offered in our data that correction of a deficit of cellular potassium directly benefits the patient. Our patients belonged to no homogenous clinical state with a known case fatality rate or a predictable prognosis. On the other hand, the rationale of replacement therapy has been to restore the patient to a normal chemical state. It appears reasonable, therefore, to attempt to put the replacement of intracellular electrolytes on the same successful basis as that which has been achieved for the constituents of the extracellular fluid.

SUMMARY

Potassium was administered in daily doses of 0.7 to 3.7 m.eq. per kilogram to six adult patients maintained on parenteral fluids. Three normal subjects on isocaloric diets were given 4.4, 3.2, and 0 m.eq. of potassium per kilogram, as controls. The daily exchanges of electrolytes and nitrogen were measured.

In four of the patients the concentrations of potassium in serum were abnormally low. All of the patients retained administered potassium in the cellular phase in excess of nitrogen in amounts varying from 1.2 to 4.6 m.eq. per kilogram. Only one patient received potassium long enough to show that a maximum degree of retention had been reached. Each of the normal subjects who received potassium retained only 0.1 m.eq. per kilogram.

During periods of low potassium intake more potassium was lost in urine than in gastrointestinal fluid. In four patients during such periods the quantity in urine was greater than was the quantity during periods when the intakes were high and concentrations in serum were normal. The minimum amounts in urine in three of the patients deprived of exogenous potassium and maintained in nitrogen equilibrium, were 28, 27 and 6 m.eq. per day, and in the normal subject 34 m.eq. per day. The potassium U/P ratio was never less than 1.0.

CONCLUSIONS

1. Adult patients deprived of potassium by gastrointestinal disorders retain significant amounts of potassium when administered.

2. Retention of potassium probably indicates cellular deficit of the ion.

3. Such deficits are frequently but not always associated with abnormally low concentrations of potassium in serum.

4. During administration of potassium to such patients the excretion of potassium tends to decrease rather than to increase.

5. The kidney in normal subjects as well as in depleted patients, under conditions of maximal need for conservation, has a limited minimal rate of excretion of the ion. This continued excretion by the kidney is an important factor in producing a state of potassium deficiency.

CAN VASCULAR SHUNTING BE INDUCED IN THE KIDNEY BY VASOACTIVE DRUGS?¹

By FRANÇOIS C. REUBI² AND HENRY A. SCHROEDER

(From the Department of Internal Medicine and the Oscar Johnson Institute, Washington University School of Medicine, and Barnes Hospital, St. Louis, Missouri)

(Received for publication July 15, 1948)

Modern concepts of renal physiology are based on the assumption that, at least in normal subjects without impotent or aglomerular tubules, nearly all the blood goes first through the glomeruli before reaching the peritubular capillaries (1). Therefore, blood supplying the tubular system is thought to come entirely from the efferent arterioles. Anatomists have described almost every kind of anastomosis, however, which could shunt various parts of the functioning parenchyma (2). Except by Spanner (3), little consideration has been given to their possible significance in the normal kidney (4-6). Likewise, very little is known of the role of renal lymphatic vessels in the function of the kidneys (7, 8).

The recent work of Trueta, *et al.* (9) aroused general interest in this subject, because for the first time³ an attempt was made to demonstrate the importance of renal vascular channels which bypass the cortex. Although these authors offer only morphological evidence and employ rather vigorous methods (crushing a limb, very large doses of epinephrine, etc.), they were able to show under these conditions a shift between cortical and medullary blood flow in the rabbit. Therefore, it seemed rewarding to investigate whether a similar phenomenon occurs in human subjects and dogs under normal or pathological circumstances, and whether, as Trueta indicated, this is related to the presence of arterial hypertension. The experiments here reported were made in order to detect, if possible, any changes in the relative blood supply of the different parts of the nephron after administration of certain drugs in pharmacologically active

doses. It was believed that the opening or closing of anastomotic channels between arteries and veins would be reflected by relative changes in the renal extraction of p-amino hippurate and/or mannitol, the utilization of oxygen, or both.

METHODS

Catheterization of the right renal vein was performed in 14 patients using the technique described by other authors (11, 12). Eight suffered from arterial hypertension and six did not. Catheters Nos. F-8, -9, or -10 were used. In four of the earlier experiments a single intravenous injection of sodium para-amino hippurate (PAH) and mannitol solutions was given as soon as the position of the catheter had been checked by roentgenograms. The concentration of the solutions was chosen so as to provide acceptable plasma levels during one hour or longer. In later experiments, a continuous infusion of PAH and mannitol was used instead of the single injection in order to provide relatively constant levels of these substances in the blood. After one, two or three simultaneous samples from the femoral artery or antecubital vein and from the right renal vein had been drawn, epinephrine or histamine was given subcutaneously, and two or three more simultaneous blood samples collected three to 45 minutes later. In one case pentothal-sodium in anesthetic dose was injected intravenously. In all experiments PAH and mannitol were determined in renal and peripheral blood. In six the oxygen content and in four the oxygen capacity and the hematocrit were also measured. All blood samples were centrifuged as soon as possible in order to avoid diffusion of PAH from red blood cells. PAH and mannitol were measured by the method of Goldring and Chasis (13) modified only as regards the technique for estimating the plasma and urine mannitol "blank" (14). The oxygen content and capacity were determined by the method of Van Slyke and Neill (15). Hematocrits were read in Wintrobe tubes. The blood pressure was measured by the auscultatory method.

In 15 dogs blood from the renal vein and from the renal artery and/or femoral artery was drawn slowly and more or less simultaneously after the vessels had been exposed under nembutal anesthesia. For technical reasons, only partial experiments could usually be performed due to the large amounts of blood necessary for complete analyses. In some dogs the arterio-venous oxygen difference and the hematocrit, and in others, the

* Corrected to a constant hematocrit of 54.75.

PAH extraction,⁴ were determined before and after the intravenous injection of epinephrine (50 to 200 gamma) using the methods described above.

RESULTS

a. *Experiments in dogs (Tables I, II).* After epinephrine was injected the difference between the oxygen content in femoral arterial and renal

⁴ The "extraction" is defined by the expression $\frac{P-R}{P}$, where P is the concentration of the substance in the peripheral and R in the renal venous plasma.

venous blood was lower in five dogs (Nos. 19, 20, 22, 29, and 106), and higher in three (Nos. 102, 105 and 112). The reaction to the drug was minimal in the latter (Table I). Renal arterial hematocrit values were consistently lower than venous, and the usual rise occurring after epinephrine was less marked than in renal venous blood. Femoral arterial hematocrit values were not consistent, being sometimes higher and sometimes lower than those from renal arterial blood. Epinephrine produced less hemoconcentration in fem-

FIG. 1. VARIATIONS IN THE EXTRACTION OF PARA-AMINO HIPPURATE BY THE RIGHT KIDNEY AFTER EPINEPHRINE WAS INJECTED SUBCUTANEOUSLY

The control values to the left of the vertical line were taken at least ten minutes apart, and after sufficient time had elapsed to allow the blood levels to come to equilibrium. The vertical line indicates the time of injection of epinephrine. Except for three cases, there is no significant change in the extraction of PAH (see Table III). Note that the reduction occurs only in the last determination. Patients F. W. and W. D. suffered from arterial hypertension, as did D. B. and V. R.

FIG. 2. VARIATIONS IN THE RIGHT RENAL EXTRACTION OF PAH AFTER THE SUBCUTANEOUS INJECTION OF HISTAMINE (—) AND THE INDUCTION OF PENTOTHAL ANAESTHESIA (---)

All patients were hypertensive but F. C. The vertical line indicates the time of injection. Note that a significant decrease occurred only in one case (E. C.), and this 23 minutes after injection.

oral arterial blood than in that from the renal vein, except in one dog (No. 231).

Changes in the oxygen capacity paralleled the hematocrit values, and the same is roughly true with regard to the plasma proteins, indicating that actual hemoconcentration occurred. Caffeine in two experiments appeared to lessen the arterio-venous hematocrit difference. The extraction of PAH by one kidney was influenced by intravenous epinephrine in four of five dogs, but the direction of the change was inconsistent (Table I). In one (No. 105) it decreased progressively, in one (No. 217) temporarily, and in two it rose. One experiment indicated a pronounced fall (No. 29) but the blood sample may have become contaminated with ureteral urine.

b. *Experiments in human subjects (Table III).* Fourteen successful experiments were completed. Renal arterio-venous differences in oxygen content were determined in six patients. After pentothal anesthesia was given in one (M. P.) the difference was slightly increased. When epinephrine

was injected it became decreased in two (W. G. and F. W.), but renal venous blood became more concentrated as evidenced by plasma protein levels. In two other subjects (P. C. and W. D.) the arterio-venous oxygen difference was increased. It was probably unchanged in patient D. B., although the second arterial determination of oxygen was not entirely reliable, a small clot having been found in the syringe. Hematocrit values, determined in four cases, were increased in two by epinephrine and in one (W. D.), this was greater in renal venous than in femoral blood. They were unchanged during pentothal anesthesia in one, and slightly increased in one after histamine was injected.

The renal extraction of PAH became decreased 16 to 40 minutes after epinephrine was injected in three subjects. This decrease ranged from 91.0 to 84.5 per cent in subject P. C., from 79.7 to 69.6 in F. W., and from 89.5 to 83.7 in W. D. (Figure 1). No significant changes were observed in six patients. After histamine was given, changes occurred in two (E. C. and A. B.), where the ex-

traction fell from 87.1 to 80.2 and from 80.7 to 77.0 respectively (Figure 2).

The mannitol extraction usually increased shortly after epinephrine was injected, suggesting that efferent arteriolar constriction occurred, returning to its previous level later (except in case F. W. where it was definitely lower in the last period). After histamine was given, it increased in three cases, and markedly decreased in one (E. C.). Variations in the one experiment during which pentothal anesthesia was induced were not consistent.

In some of these patients urine was collected during the renal venous catheterization, and the urinary excretion of mannitol and PAH was compared with their renal extraction. A discrepancy between the plasma flows calculated from C_M/E_M and C_{PAH}/E_{PAH} was found (16). This discrepancy cannot be explained by the presence of arteriovenous shunts, as the extraction percentages of these materials were not unduly altered. These results will be reported elsewhere (17).

DISCUSSION

It is conceivable that shunts of several types exist in the kidney. It could reasonably be expected that our experiments would be capable of demonstrating at least three of them, if they were physiologically important and responded to ordinary doses of vasoactive drugs, namely:

1. *Direct arterio-venous anastomoses between relatively large vessels (arcuate or interlobular), arteriola rectae, "juxta-medullary by-passes"* (9, 18), which short-circuit both glomeruli and tubules. Opening of these shunts would decrease PAH and mannitol extractions and renal arteriovenous oxygen differences.⁵ This was not found to be the case.

⁵ It is possible that "juxta-medullary by-passes" resulting from blood flowing through nephrons in this region, produce about the same effect as direct arteriovenous shunts. It is not likely that glomeruli, which have efferent arterioles as large as afferent (9), perform much filtration, and therefore little mannitol would be filtered. Even if the tubules corresponding to these glomeruli are functioning, relatively small amounts of PAH will be extracted from the blood by the tubular cells, unless there is an adequate intratubular flow of urine. Moreover, the proportion of juxta-medullary nephrons to cortical ones is probably not greater than 10 per cent (18). Therefore, if these nephrons should become

2. *Vessels supplying the tubules by-passing the glomeruli.* Opening of these would decrease the mannitol extraction alone, PAH and oxygen differences remaining unchanged. The same effect would be produced by the presence of "aglomerular tubules" (1). Changes in the mannitol extraction, however, were not consistent.

3. *Direct communications between efferent glomerular arterioles and renal veins by-passing the peritubular capillaries.* Opening of such anastomoses would decrease the PAH extraction and decrease slightly the oxygen differences, mannitol extraction being unchanged. One would expect the same from "impotent nephrons" (1). Extractions of PAH, however, remained relatively constant in most cases.

It is also conceivable that some of the substances entering the kidney leave it via lymphatic vessels and by-pass the renal vein either after being reabsorbed, or after interstitial diffusion. Unfortunately, there is at present no innocuous way to demonstrate such a mechanism in man.

The first type of shunt should be easily demonstrable and would probably be the most important in physiopathological conditions of the kidney. There is some evidence that such shunts exist, at least in animals. Trueta claims to have seen "red blood" in the renal veins of rabbits (9). We have observed it in dogs only during trauma to the kidney at operation. Unexplained low PAH or diodrast extractions have been observed both in the dog and in man (12, 19, 20). The existence of shunts has been postulated in order to explain "reflex anuria" (21), and the "crush syndrome" (9). These observations have been made usually under experimental, operative or severe pathological conditions. The importance of anastomoses would be greater if they were concerned with ischemia of certain parts of the kidney, and if relatively mild stimuli (nervousness, autonomic instability, emotional factors, pain) would be able to shift the cortical circulation to a medullary one. For that reason, epinephrine was used in our experiments. Histamine was employed as well, because a renal action somewhat similar to that of epinephrine has been demonstrated (22).

functional to any great extent, at the expense of the cortex, one might expect a considerable depression of the extraction of both mannitol and PAH.

When renal arterio-venous oxygen differences were measured in the dog, Trueta's findings appeared to be confirmed, *i.e.*, the oxygen content in renal venous blood increased after the intravenous injection of epinephrine. However, when hematocrit, oxygen capacity and plasma proteins were also determined, (Table I), it appeared that this increase was simulated by a marked hemoconcentration (according to oxygen capacity and hematocrit), of as much as 22.2 per cent in the renal blood, and of only 4.4 per cent in the peripheral blood in one case (Figure 3). The increase in plasma proteins was not as striking. When arterio-venous differences were corrected to a constant oxygen capacity, epinephrine appeared to cause an increase (from 2.2 to 4.7 volumes per cent). We observed the same increase in experiments in which mild reactions to epinephrine were elicited and negligible hemoconcentration occurred (Nos. 102, 105, and 112).

However, only renal venous and femoral arterial blood were compared. According to Dole, *et al.* (23) unexplained differences in the oxygen capacity of renal and peripheral blood can be observed in the dog. Therefore, in later experiments samples were drawn simultaneously from the renal vein, renal artery, and sometimes from the femoral artery. At variance with the assumption of Dole, it was found that there was a consistent difference between venous and arterial renal hematocrits (and oxygen capacities), the former being more concentrated. This difference was increased by epinephrine and decreased by caffeine (Nos. 116 and 117). This hemoconcentration cannot be entirely explained by the amount of excreted urine. With a diuresis of 0.5 cc. per minute, the expected hemoconcentration would be only 0.5 per cent. Even if epinephrine reduces renal blood flow more than urine flow, hemoconcentration greater than 2 or 3 per cent is not likely. Therefore, some loss

§ RV—FA.

femoral and renal venous blood were compared. In the dog there may be a discrepancy between femoral and renal arterial samples. At any rate, under control conditions, there were no significant differences between femoral arterial and renal venous hematocrits in man.

In the evaluation of renal arterio-venous oxygen differences one point must be emphasized. Reduction of blood flow may decrease greatly the oxygen content of the venous blood and partial shunting may partly compensate for this change. For that reason, unless opening of large shunts

occurs, these determinations are of less value than PAH and mannitol extractions.

Changes in PAH extractions in dogs were not very consistent after epinephrine was given, and the results are not conclusive. In one case (No. 29) it fell to a very low value, but errors in technique cannot be excluded. Except for this single questionable case, there appeared no changes consistent with the opening of shunts. The results of human experiments are certainly less questionable, and due to the standard conditions under which the tests were performed, even slight variations can be considered significant. It may be assumed that partial shunting of the first type was produced by epinephrine in case F.W. (Table III), as both the PAH and the mannitol extractions were lower than the control values (11.4 and 33.3 per cent respectively). In cases P. C. and W.D., where the PAH extraction was reduced 7.1 and 6.7 per cent, the mannitol extraction was not affected, so that shunting might have excluded mainly the peritubular capillaries (type of shunting No. 3). Impairment of tubular excretory capacity due to anoxia, however, could account for this reduction (26).

Pentothal anesthesia was without visible effect in one case, and histamine may have opened shunts of the first type in one (E. C.) and of the third type in another (A. B.). At any rate, the greatest shunting elicited in one case where the reaction to epinephrine was severe, was not much more than one-tenth of the total renal blood flow. Moreover, this phenomenon was observed in a diseased kidney where the extraction was low at the beginning. Although four out of the five patients in whom changes occurred had hypertension, our findings do not support the hypothesis of Trueta, *et al.* that large shunts may open under physiological conditions and be responsible for intermittent cortical ischemia concerned in hypertensive disease. Bradley and Bradley (27) were unable to demonstrate appreciable reduction in PAH extraction after abdominal compression in eight normal subjects, although renal blood flow was reduced. While a persistently low PAH extraction by damaged hypertensive kidneys could be produced by permanent shunting, tubular impairment and the destruction of active parenchyma with subsequent replacement by fibrous tissue seems a more likely explanation. Shunts of that kind would not have

any etiologic significance, being the result and not the cause of the renal alterations.

Although these experiments do not disprove the presence of arterio-venous by-passes in the kidney of man and of the dog, they do indicate that after doses of epinephrine or histamine large enough to cause systemic reactions, these vascular channels do not consistently appear. When they do, they are not very important. In the dog, furthermore, they were not demonstrated even after large doses of epinephrine. It is still possible that such channels may become functional following toxic doses of drugs, during severe shock, or after crushing wounds. Their significance in minor physiological alterations in homeostasis is therefore questionable.

SUMMARY AND CONCLUSIONS

1. Experiments involving determinations of PAH, mannitol, oxygen content and hematocrit in renal venous and peripheral (or renal) arterial blood before and after injection of epinephrine, histamine or pentothal were performed in eight hypertensive and six normotensive patients, and in 15 dogs. In patients, renal venous blood was collected by catheterization of the right renal vein.

2. The maximal decrease in the extraction of PAH by the kidneys of patients after subcutaneous injection of epinephrine or histamine was 11.4 per cent; dog experiments were inconclusive.

3. In two human subjects, arterio-venous oxygen differences were increased by epinephrine, and in three, decreased.

4. In dogs, there was a consistent difference in the oxygen capacity, hematocrit, and plasma protein content between renal arterial and renal venous blood, the latter being more concentrated. This difference was increased by epinephrine. It is suggested that this loss of fluid from the renal blood may have occurred through renal lymphatic vessels or other vascular channels by-passing the renal vein.

5. From these experiments it can be concluded that large intermittent renal shunts can not be elicited in man by physiological doses, or in dogs by larger doses, of epinephrine. Even in subjects with essential hypertension, histamine or epinephrine produced relatively small and inconsistent changes which could be ascribed to the presence of shunts.

ACKNOWLEDGMENTS

Determinations of para-amino hippurate and mannitol were made under the supervision of Dr. Palmer H. Fletcher, whose help is appreciated. The technical assistance of Miss Ellabeth Houghton, Mrs. D. Heady, and Miss Ruby M. Brooks, R.N., is gratefully acknowledged.

ELECTROPHRENIC RESPIRATION. II. ITS USE IN MAN¹

By JAMES L. WHITTENBERGER, STANLEY J. SARNOFF, AND
ESTHER HARDENBERGH

(From the Department of Physiology, Harvard School of Public Health, Boston)

(Received for publication August 6, 1948)

In a previous investigation it was shown that artificial respiration could be effectively administered to the cat, dog, monkey and rabbit in the absence of spontaneous respiration by electrical stimulation of one or both phrenic nerves (1, 2). During the development of the applications of the technique, an opportunity occurred for testing the method in man. A patient with severe chronic, diaphragmatic flutter was operated on for the purpose of 1) crushing the left phrenic nerve and 2) temporarily blocking the right phrenic with procaine. At the time of operation a single, slender, multiple-strand, plastic-covered wire was spirally wound around the right phrenic nerve in its exposed portion and the other end of the lead wire was brought out through a simple needle puncture wound about 2 cm. lateral to the site of incision. The operation was performed under local anesthesia. Five hours later, electrophrenic respiration was begun.

The method is described in detail in a previous communication (2). Briefly, it is the following. An ECG plate secured at the wrist functions as an indifferent electrode for the single stimulating electrode on the phrenic nerve. The stimulating current is derived from a Grass stimulator set for a frequency of 40/sec. and an impulse duration of 2 milliseconds. The current is run through a rotating potentiometer which rhythmically varies the voltage in such a way as to cause the diaphragm to perform a gradual contraction and relaxation similar to that which it performs during spontaneous breathing.

Air flow patterns were obtained with the pneumotachograph developed by Silverman (3) and Silverman and Whittenberger (4). From the pneumotachogram one is able to derive information related not only to the rate and contour of the respiratory pattern but also precise values for the patient's ventilation volume. The level of arterial oxygen saturation was observed throughout the period of phrenic nerve stimulation by means of the Millikan oximeter (5).

The experiments on this patient were designed to achieve five objectives:

1. To ascertain whether electrophrenic respiration could maintain minute volumes equal to or

greater than the spontaneous resting minute volume with submaximal stimulation of one phrenic nerve.

2. To ascertain the ease with which a smooth diaphragmatic motion can be obtained in man.

3. To find out if the unanesthetized patient would cease spontaneous respiratory activity when adequate aeration was supplied by means of phrenic stimulation (as was previously found to be the case in the experimental animal under anesthesia).

4. To estimate the amount of pain or discomfort produced by effective electrical stimulation of the phrenic nerve.

5. To ascertain whether adequate arterial oxygen saturation could be maintained with the submaximal stimulation of one phrenic nerve.

RESULTS

1. Figure 1 shows the pneumotachograms of A) spontaneous respiration and B) electrophrenic respiration. Table I compares values obtained

TABLE I
*Respiratory measurements during spontaneous breathing
and electrophrenic respiration*

	Spon- taneous respira- tion	Electro- phrenic respira- tion
Rate per minute	26.6	23.3
Minute volume in liters	5.18	7.52
Tidal volume in liters	0.195	0.323
Average flow rate during inspiration, in liters per minute	12.0	15.9
Ratio of time of inspiration to time of total respiratory cycle, in per cent	43.1	47.3

during spontaneous respiration and electrophrenic respiration for respiratory rate, minute and tidal volumes, average flow rate during inspiration, and the fraction of the respiratory cycle taken by the inspiratory phase. These results were obtained at a rate of artificial respiration slightly slower than the patient's spontaneous rate and with submaximal stimulation of one phrenic nerve. It can be

¹ Aided by a grant from The National Foundation for Infantile Paralysis.

seen that an exchange of air significantly larger than the patient's spontaneous exchange is readily achieved at a slower than the spontaneous rate. A still larger exchange of air resulted from maximal stimulation. It was established in this patient, as in the experimental animal, that the depth of respiration is proportional to the peak voltage applied. The regularity of the tracing in Figure 1B indicates that the patient was not contributing to the respiratory effort. This phenomenon will be discussed later.

2. It is apparent from Figure 1B that the diaphragmatic contraction produced by electrical stimulation of the phrenic nerve in this patient was a smooth motion. (The minor irregularities during diaphragmatic relaxation in the record are due to the diaphragmatic flutter.) A smooth inspiratory curve was, in fact, predicted from the theoretical basis on which electrophrenic respiration is based; namely, that increasingly forceful contraction of the diaphragm results from the spread of current to include more and more fibers of the phrenic nerve as the voltage is increased. Since the phrenic nerve in man is a single trunk and is considerably larger than that of the experimental animal, a graded voltage spread is more easily and smoothly obtained. As observed visually, the movement of

the right diaphragm resulting from phrenic nerve stimulation closely resembled that seen during spontaneous respiration.

3. It was apparent from simple observation of the patient that during artificial respiration there was no respiratory effort other than that of the right diaphragm, which resulted from electrical stimulation. In order to obtain graphic evidence of this fact, two additional maneuvers were carried out. Figure 2 is a pneumotachogram of spontaneous respiration interrupted by the onset of electrical artificial respiration. There is no evidence that spontaneous respiratory activity occurred after phrenic nerve stimulation had been started. Spontaneous activity would be evident as irregularities in the pattern. The reverse sequence was employed to find out whether, upon abruptly terminating artificial respiration, the lack of spontaneous respiratory activity would be apparent from the lack of air flow as registered on the pneumotachogram. Figure 3 is the result. Artificial respiration was stopped at the signal and it can be seen that no respiratory activity was present until the apnea had persisted for over 16 seconds. Breathing then returned with a gradual increase in amplitude until it regained its pre-stimulus contours. This interesting observation, namely, that

FIG. 1. A, PNEUMOTACHOGRAM OF SPONTANEOUS RESPIRATION; B, PNEUMOTACHOGRAM DURING ELECTROPHRENIC RESPIRATION

Area under the curve represents volume of air flow during inspiration; the area above the base line represents expiration.

FIG. 2. PNEUMOTACHOGRAM OF SPONTANEOUS RESPIRATION INTERRUPTED BY THE ONSET OF ELECTROPHRENIC RESPIRATION

Phrenic nerve stimulation was started at the signal. The two strips are continuous.

FIG. 3. APNEA INDUCED BY ELECTROPHRENIC RESPIRATION

The patient was on artificial respiration at the start of this pneumotachogram. At the signal, phrenic stimulation was discontinued and the tracing shows the absence of spontaneous respiratory effort during the period immediately following cessation of artificial respiration. The minor irregularities are due to the diaphragmatic flutter. The three strips are continuous.

the individual completely relinquishes spontaneous control of respiration while on electrophrenic respiration, is not yet fully explained. Animal experiments in which blood gas tensions were observed indicate that the prompt cessation of spontaneous respiration is not due to a fall in carbon dioxide brought about by overventilation. The neural pathways involved in this phenomenon are being investigated.

4. The evaluation of pain in this patient was not easy. During phrenic nerve stimulation the patient experienced discomfort referred to the right shoulder along the ridge of the trapezius muscle. This information was obtained only on direct questioning, was never volunteered. The patient did not appear to be in pain and fell asleep several times during the longer periods of artificial respiration. Conclusions as to the degree and importance of the intensity of the discomfort produced will have to be deferred until a variety of patients have been studied.

5. It was thought, prior to our experience with this patient, that the relatively stable mediastinum of the human subject might prevent the adequate aeration of the contralateral lung when only one phrenic nerve was stimulated, even though reasonable respiratory minute volumes were achieved. In order to obtain evidence in this matter, arterial oxygen saturation (by the oximeter method) was observed during spontaneous respiration and during artificial respiration in the absence of spon-

taneous respiratory activity. Figure 4 shows the results. It is clear that a small but definite rise in arterial saturation occurred within 60 seconds of the onset of electrophrenic respiration. A rise of 1 per cent in saturation at the upper range of the oxyhemoglobin dissociation curve indicates a rise of 10 mm. Hg or more in the mean effective alveolar partial pressure of oxygen. This signifies an improvement in lung ventilation out of proportion to a 1 per cent rise in oxygen saturation. The oximeter was calibrated by having the patient inhale 99.6 per cent oxygen.

Artificial respiration by phrenic nerve stimulation was induced in this patient for several periods varying in length from five to 76 minutes on two occasions during the five days following electrode application. The procedure apparently resulted in no functional damage to the nerve, since fluoroscopic examination of spontaneous diaphragmatic activity on the day of electrode removal revealed excursions equal in amplitude to those observed before the experiment.

CONCLUSIONS

1. Artificial respiration by phrenic nerve stimulation can be performed in man.
2. A smooth, gradual, diaphragmatic contraction occurs when an increasing voltage is applied to the phrenic nerve. The diaphragm thus performs a motion closely resembling that which performs during natural inspiration.
3. Respiratory minute volumes in excess of patient's spontaneous minute volumes can readily be obtained with the submaximal stimulation of one phrenic nerve.
4. The depth of respiration is proportional to the peak voltage applied to the phrenic nerve man as in the experimental animal.
5. Adequate oxygenation of the blood can be maintained by electrophrenic respiration in the absence of spontaneous respiration.
6. The human subject, like the experimental animal, completely relinquishes spontaneous control of respiration when electrophrenic respiration is induced.

THE VOLUME OF THE LUNG DETERMINED BY HELIUM DILUTION. DESCRIPTION OF THE METHOD AND COMPARISON WITH OTHER PROCEDURES

BY GEORGE R. MENEELY AND NOLAN L. KALTREIDER

(From the Department of Medicine, School of Medicine and Dentistry, University of Rochester, the Medical Clinics of Strong Memorial and Rochester Municipal Hospitals, Rochester, N. Y., and the Heart-Lung Station¹ of the Department of Medicine, Vanderbilt University School of Medicine, Nashville, Tenn.)

(Received for publication July 3, 1948)

INTRODUCTION

The use of the foreign gas, helium, for determination of the pulmonary capacity has been reported previously in preliminary form (1). The present report concerns further experience with this method and comparison of results obtained with results by the Christie method (2) and by the Lassen, Cournand, and Richards modification of the Christie method (3, 4) in normal and emphysematous subjects.

Foreign gas methods for measurement of the residual air or mid-capacity are not new. Van Slyke and Binger (5) employed hydrogen for this purpose. These authors emphasized the danger of explosion with hydrogen-oxygen mixtures and of occasional contamination of hydrogen with arsine. Oxygen dilution methods, especially the method of Christie (2), displaced the foreign gas method. Lassen, Cournand, and Richards (3, 4) noted an "Oxygen Storage Effect" which they believed introduced errors in the determination of pulmonary capacity by Christie's method especially in patients with large mid-capacities. To correct this error, they modified the calculation by Christie's method to allow for observed differences in the concentration of nitrogen between the alveolar air and the spirometer circuit at the end of the rebreathing period. McMichael in England (6) modified the Christie method by matching the oxygen consumption of the subject with a controlled inflow of oxygen so that the total volume of the lung and the spirometer circuit remained constant throughout the rebreathing period. He proved this alteration abolished the "Oxygen Storage Effect."

More recently, McMichael (7) reintroduced the foreign gas principle employing hydrogen and the

warm wire thermal conductivity katharometer for the analysis. He continued the constant volume feature of his earlier method. The use of a foreign gas with a thermal conductivity quite different from that of oxygen and nitrogen greatly facilitated the determination because it eliminated the separate gas analysis at the end of the rebreathing period. The analysis is continuous with the katharometer and the final concentration is read directly from a meter.

Helium, with a thermal conductivity hardly different from that of hydrogen (Table I), eliminates the danger of hydrogen-air mixtures (which are less now than when first emphasized by Binger and Van Slyke) without sacrifice of the merit of McMichael's method. Since publication of our preliminary article, Behnke (8) has mentioned a method employing helium for the determination of the pulmonary capacity by a "washing out" procedure, which is not related to the method here described except in that helium is used. It is more closely related to the "open" method of Cournand and Richards (9, 10).

APPARATUS AND PROCEDURE

The spirometer circuit is diagrammed in Figure 1. The seven-liter cylindrical spirometer with obliterated internal dead space writes the respiratory tracing on a kymograph drum. The volume of the spirometer may be read from the scale and pointer and, by transfer, from the respiratory tracing itself. The subject is connected to the circuit through a rubber mouthpiece on a three-way valve. The expired air passes vertically through a soda-lime canister for most efficient absorption of carbon dioxide. Oxygen may be added at any desired rate through the diaphragm type flow control and meter on a tank of "medical" oxygen. A blower impels

¹ This laboratory was organized under a grant from Commonwealth Fund.

FIG. 1. SPIROMETER CIRCUIT FOR DETERMINATION OF THE VOLUME OF THE LUNG USING HELIUM

he expired air through the water bottle which contains many glass beads to break up the bubbles, resaturate the gas mixture, and prevent disagreeable bumping due to large bubbles. Provision is made for the introduction of helium at the spirometer outlet. Part of the return flow shunts through the analytical cell and returns via the cell outlet to rejoin the return stream. The pressure differences in different segments of the circuit are small: slight negative pressure obtains between the soda-lime and blower, and positive pressure elsewhere. The soda-lime and the water bottle isolate the blower to a degree, preventing vibration of the air column at the mouthpiece.

The dead space of the circuit was determined by rinsing with air, emptying the spirometer, adding a volume of oxygen and mixing with the blower. The final concentration of nitrogen of the dead space air plus added oxygen was determined on the Van Slyke manometric apparatus and the volume corrected for temperature and barometric pressure. Care must be taken to keep the dead space constant by maintaining the water levels in the spirometer and the water bottle.

The oxygen inflow is adjusted to match the oxygen consumption of the subject by taking a short preliminary respiratory tracing, and setting the valve appropriately. This period also acustoms

the subject to rebreathing. Complementary and reserve volume can be recorded at this time. Any desired volume of helium may be measured in the graduate and delivered into the spirometer by directing the flow with the stopcock at the spirometer base into the spirometer and opening the water reservoir valve. Observations indicated that differences in temperature between the graduated cylinder and the spirometer introduced an error of less than 0.5 ml. in measurement of the helium added. Since this volume was ordinarily 700 ml., this is a negligible error.

The analytical cell² is similar to those used for airplane engine exhaust gas analysis (Figure 2). Complete saturation of the gas mixture is assured by a wet cotton filler in the cell antechamber. When the current through the bridge is maintained constant, and only one component of the gas mixture varies, the indicating meter may be calibrated to indicate the concentration of the gas. For ordinary use, dry cell batteries furnish a suitable cur-

² Cambridge Instrument Co., New York, N. Y. The design of this cell is such that all four chambers are maintained at the same temperature and the chambers containing the standard gas are at atmospheric pressure. The chambers containing the gas to be measured are at the pressure which obtains in the spirometer circuit which is also atmospheric. Gas enters the cells by diffusion, thus eliminating errors due to flow.

FIG. 2. DIAGRAMMATIC CIRCUIT OF THE KATHAROMETER CELL

rent source. For the extensive studies reported here, the apparatus was in virtually continuous use and a current-controlled power pack was developed which proved more satisfactory. The circuit of the analytical cell and power pack are shown in Figures 2 and 3. With a suitable switching circuit the same meter may readily be used to read the current applied to the bridge as well as the deflections due to imbalance of the bridge.

The analytical cell was calibrated over a range of 0 to 15 per cent of helium by adding measured amounts of helium from the graduated cylinder to measured volumes of air in the spirometer circuit.

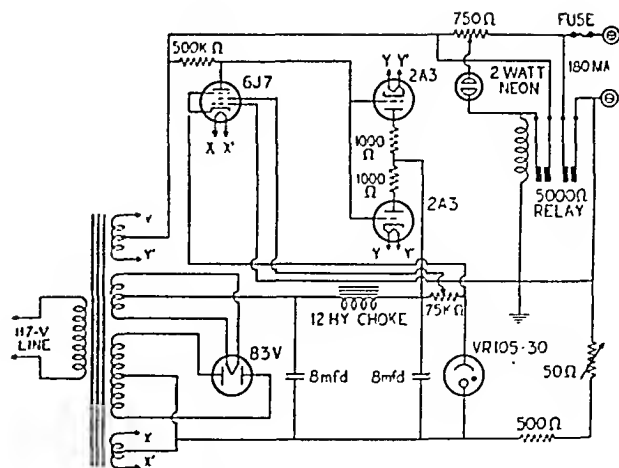

FIG. 3. CIRCUIT OF THE CURRENT CONTROL POWER PACK

Observations during this process, made with the wet and dry bulb thermometers, indicated that unless the water bottle was in the circuit, the saturation of the circulating gas mixtures with water vapor might fall to 70 or even 50 per cent due to the drying action of the soda-lime. The analytical cell is sensitive to variations in water vapor as to any other gas and thus, for calibration and checking at least, the water bottle is necessary. The water bottle also helps prevent heating due to the blower. Calibration by this means is only absolute if the helium is pure, and in this case, 1.8 per cent

FIG. 4. GRAPH FOR CORRECTION OF METER READING FOR CHANGES IN OXYGEN CONCENTRATION

of "other gases" unspecified were said to be present in the helium.³ There were no means at our disposal to investigate this point more fully, but error is not introduced because the analytical apparatus is used in the same manner as it is calibrated, and the major concern is with observed, not absolute values. Thus 700 ml. from such a supply contains 687.4 ml. of helium.

It proved impossible to match the oxygen consumption of the subject perfectly in every instance and variation in oxygen concentration within the circuit from the beginning to the end of the rebreathing period introduced a small but detectable error, which unfortunately varied depending upon the concentration of helium. Therefore the cell was further calibrated for variation due to oxygen concentration over the range of variation of helium used. This calibration was expressed graphically (Figure 4). A meter correction was obtained by entering this graph with the observed change in oxygen determined from spirometer circuit volume changes and the volume (X + B) obtained as described below.

ANALYTICAL ERROR

The accuracy of the helium analyzer was investigated. This cannot be done by the same means as as that used in calibration because, in this case, there is error in the preparation of the gas mixture due to error in measuring the air in the spirometer and error in the measurement of the helium added to the spirometer as well. Accuracy in calibration depends upon averaging a number of determinations over the whole range. To test the reproducibility of the helium analyzer a tank of

approximately 10 per cent helium in air was obtained.⁴ This mixture of constant composition was bubbled through water several times and then allowed to flow through the analytical cell which was disconnected from the spirometer circuit for this purpose. The procedure was repeated over a period of several months and the observed concentrations determined with the cell were analyzed statistically (Table II). The mean of these observations which was taken as the "true" concentration of helium in the tank of gas was 10.15 volumes per cent helium with a standard deviation of ±0.071 volumes per cent. Then the analytical "error" in 95 per cent of cases would be less than ±0.15 volumes per cent or 1.5 per cent (11).

This error was compared with the standard error of the analysis for nitrogen in spirometer mixture and alveolar air samples by statistical analysis of 103 serial pairs of duplicate analyses for nitrogen made on the Van Slyke manometric apparatus during this study. One-half of the difference between duplicates was taken as the deviation from "truth." The standard error was ±0.103 volumes per cent. There was no correlation between the magnitude of the error and the concentration of nitrogen. At 80 per cent nitrogen, 95

⁴ Ohio Chemical Company.

per cent of "errors" would lie between ± 0.26 per cent and at 50 per cent nitrogen between ± 0.42 per cent. Thus the analysis for helium by the katharometer carries more error than the analysis for nitrogen in the Van Slyke manometric apparatus, when compared by this method.

MIXING TIME

We investigated the rate at which equilibrium is attained in rebreathing a helium mixture by observing the concentration of helium indicated by the meter at one-minute intervals after turning the subject into the spirometer circuit containing 5,500 ml. of 12.5 per cent helium in air while

keeping the volume constant by adding oxygen at the rate of the subject's oxygen consumption. In these observations, no allowance was made for lag in the meter which does occur because diffusion must take place from the meter antechamber into the cells in the analyzer block. The results of this investigation are shown in Figure 5. At the end of seven minutes equilibrium has been reached in the group with mid-capacities such that lung plus spirometer volume is less than 8 liters. When this volume is larger, there is a notable difference between the six- and the seven-minute concentrations of helium. When the final lung plus spirometer volume equals 9 or 10 liters, the concentration of

FIG. 5. CONCENTRATION OF HELIUM AT INTERVALS OF ONE MINUTE DURING REBREATHING A 12.5 PER CENT MIXTURE OF HELIUM IN AIR

helium appears still to be falling at a rate of approximately 0.1 per cent of helium per minute. From these observations we might conclude there is an error due to incomplete mixing of helium in the lung in those subjects with large mid-capacities. However, for practical purposes this is not the case. Comparison was made of seven-minute and ten-minute runs in determining the mid-capacity and there is no important or consistent difference (Table III). McMichael (7) read the hydrogen concentration when the "concentration no longer fell" but in some of our normal subjects there was often a small but detectable change in meter deflection, even after 30 minutes of rebreathing. Other factors, especially leaks, begin to be important in prolonged periods of rebreathing. Spirometer circuits are, after all, only relatively gas-tight, and helium has a very marked tendency to escape, due to its low viscosity and other physical properties. Extra precautions against leakage are especially important when using helium. All joints in our

equipment were closely fitted and sealed with Gylptal.⁵

The relation of the data presented in Figure 5 to the pulmonary emptying rate data of Cournand, Baldwin, Darling, and Richards (10) is obvious. It should be remembered, however, that the helium meter reading lags behind the actual concentration changes in the spirometer circuit gases and that these in turn are doubtless different from

⁵ General Electric Company.

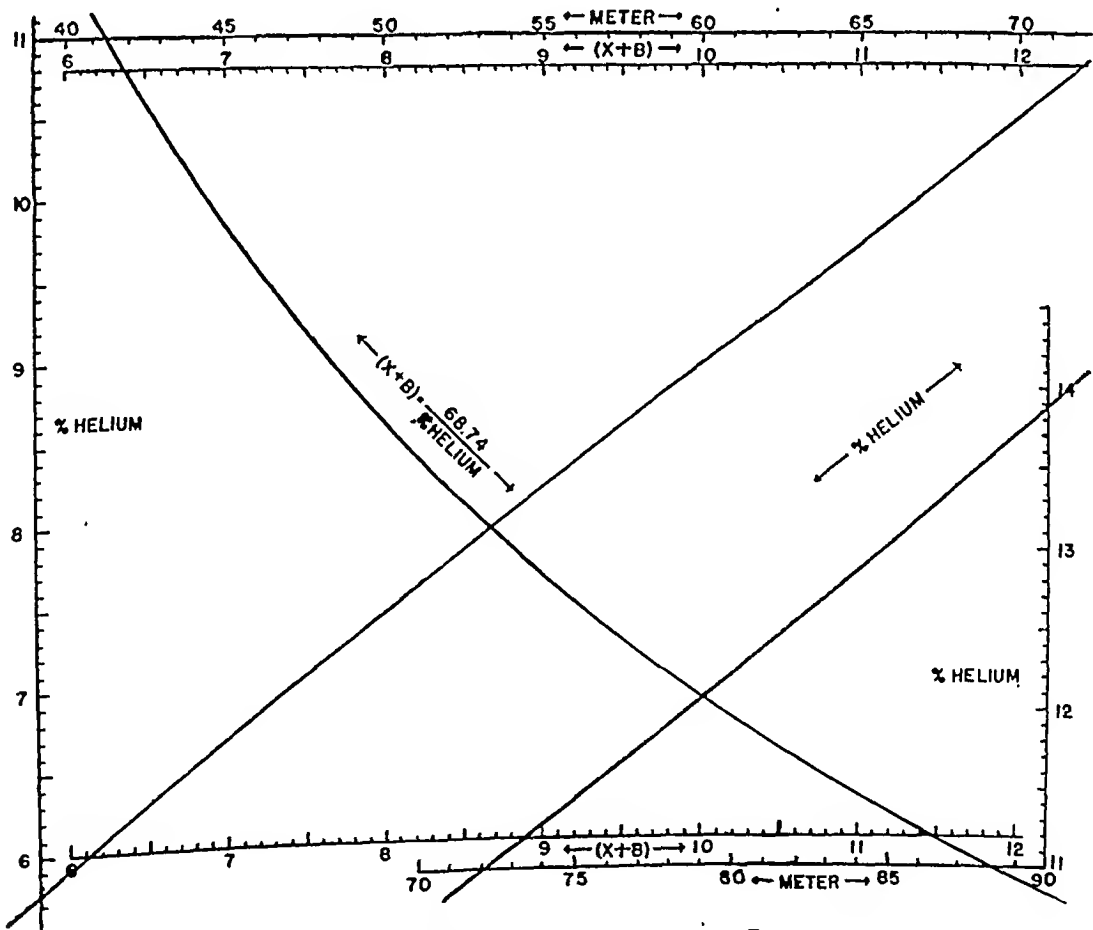

FIG. 6. GRAPH FOR CONVERSION OF METER READING INTO CONCENTRATION OF HELIUM AND TO VOLUME DISTRIBUTION OF HELIUM

alveolar helium concentration changes. Despite this, since conditions affecting this relation are relatively constant, much the same conclusions may be drawn from these curves as from the much more laborious pulmonary emptying rate procedure.

REPRODUCIBILITY

Table IV exhibits 22 pairs of determinations in normal subjects and 13 pairs in emphysematous patients. The difference between duplicates can be used to assess reproducibility of a method (11). The "error" is ± 0.084 liters in normals and ± 0.119 liters in emphysematous patients. When these are corrected for sample size (11) it is found that the "standard error" of a single determination will be less than ± 0.174 liters in normals and less than ± 0.258 liters in emphysematous patients in 95 per cent of cases. Consequently, the error of the mean of a pair of duplicates will be ± 0.123 liters and ± 0.182 liters in normal subjects and emphysematous subjects, respectively, in 95 per cent of cases.

Reproducibility of the method from day to day may be assessed from Table V. The mid-capacity determined in duplicate on different occasions shows deviations of approximately the order of magnitude to be expected from the analysis in the preceding paragraph. "Error" in terms of per

(3, 4) were carried out in the usual way. After these determinations were complete, the subject rested while the oxygen flow valve was adjusted to allow an inflow of oxygen into the spirometer circuit equal to his observed oxygen consumption. Turning off the stopcock between the oxygen tank flow control and the spirometer circuit (see Figure 1) stops the oxygen flow without disturbing the flow rate setting. The spirometer circuit was again well rinsed with room air, and the helium meter turned on. With the current through the bridge set at the standard value, the meter was adjusted to indicate zero with the balancing resistance on the cell (Figure 2). The spirometer circuit was brought to a volume of 4,800 ml. with air, and 700 ml. of helium were added from the graduated cylinder. Two hundred ml. of oxygen were then added to bring the oxygen concentration back to that of room air. As the blower mixed these gases, the helium meter deflected to indicate a concentration of 12.5 per cent helium, confirming the proper functioning of this instrument. Now the subject was allowed to rebreathe for seven minutes. Oxygen flow into the circuit at the previously determined rate was started simultaneously with turning the valve directing the subject into the spirometer circuit. At the end of rebreathing, the subject was turned back to room air and the oxygen flow stopped simultaneously. The subject was disconnected; the temperature was recorded. A few moments were allowed for absorption of carbon dioxide while circulation by the blower continued. Then the final meter reading was recorded. The relation of the initial and final lines on the kymograph tracing to the spirometer scale were recorded. These then constitute a record of the volume changes of the bell. This whole procedure was repeated after a suitable rest period.

Finally, the subject was again connected to the spirometer circuit, and while the kymograph recorded the respiratory tracing, the subject made several maximal expirations with periods of quiet breathing between, then several maximal inspirations. From this tracing the complementary air and reserve air were measured.

Calculations and corrections

The mid-capacity by the original Christie method was calculated from the equation:

$$MC = \frac{N(D + O) - (0.791D + C)}{(0.791 - N)}$$

where MC = mid-capacity.

D = volume of dead space in ml.

O = volume of O₂ in ml. added originally minus O₂ absorbed.

N = per cent concentration of nitrogen in spirometer at end divided by 100.

C = correction for nitrogen in the oxygen added originally for respiratory quotient and for nitrogen excreted from the body during rebreathing.

The modification of Lassen, Cournand and Richards was calculated from this equation:

$$MC = \frac{N(D + O) - (0.791D + C)}{\bar{a} - \bar{p}}$$

where \bar{a} = per cent nitrogen concentration in alveolar air before rebreathing divided by 100.

\bar{p} = per cent nitrogen concentration in alveolar air after rebreathing divided by 100.

Calculation of the mid-capacity by helium required first that the meter reading be corrected for gain or loss of oxygen observed in the respiratory reading (Figure 4). With this corrected value the following equation could be used although graphic methods were actually employed in practice:

$$MC = \frac{QHe}{CHe} - SV$$

where: SV = spirometer circuit volume, i.e., dead space plus spirometer bell volume at expiration.

QHe = ml. helium added before rebreathing.

CHe = final helium per cent concentration divided by 100. This concentration can be obtained from calibration graph entered with the meter reading corrected for changes in O₂ concentration (Figure 6).

Since 0.700 liters of tank gas containing 0.6874 liters of He are always added, the numerator of the above fraction is fixed.

All these mid-capacities must be corrected for temperature, water vapor, and barometric pressure. For this the customary equation was used:

$$MC \text{ cor.} = MC \text{ obs.} \times \frac{(760 - P_t)}{(760 - 45)} \times \frac{(273 - 37)}{(273 - T)}$$

where MC cor. = mid-capacity corrected for temperature and barometric pressure.

MC obs. = mid-capacity observed.

T = final spirometer temperature in degrees C.

P_t = partial pressure of water vapor in mm. of Hg for T.

45 = partial pressure of water vapor at body temperature 37° C.

In actual practice graphic methods as introduced by McMichael (6) were used. Figure 6 is a composite graph of the relation between the meter reading, the concentration of helium, and the volume in which 0.6874 liters of helium must be distributed if the concentration is as indicated. The upper horizontal line of the graph was entered with the meter reading and a perpendicular dropped from this reading to the helium concentration line. From this

point, by reading horizontally to the helium scale, the concentration of helium could be obtained. At the point where this horizontal intercepted the curved line denoting the volume of distribution of helium, one may read vertically to the horizontal scale of values for $(X + B)$, which represents the total volume of lung and spirometer system. However, this reading is in error due to variation in oxygen concentration. The observations of variation of meter reading for variation in oxygen concentration were converted into a graph in terms of oxygen gained or lost for various values of $(X + B)$: that is, at various concentrations of helium (Figure 4). The tentative value of $(X + B)$ together with the oxygen gained or lost was used to enter Figure 4 to obtain a meter correction for oxygen. With this new corrected meter reading, the composite graph (Figure 6) was again entered, reading vertically from the meter scale to the helium concentration line, then horizontally to the volume of $(X + B)$ curve, thence vertically to the scale of $(X + B)$. $(X + B)$ corresponds to $\frac{Q_{He}}{C_{He}}$, X corresponds to mid-capacity and B corresponds to SV, the spirometer circuit volume.

The helium mid-capacity requires further correction. The dead space of the mouthpiece and valve was about 2 liters for the mid-capacity, there is an apparent increase of 30 ml. in the mid-capacity due to differences in concentration of inert gases between the lung and the spirometer system. In our earlier report (1) we stated that 10 ml. of helium were absorbed by the body during the period of rebreathing. Extension of the experiments by which we arrived at this figure cast doubt upon their validity. Ten ml. of helium distributed in a volume of approximately 8 liters of lung plus spirometer circuit, is not easy to find by analysis for differences in concentration, for at a helium concentration of around 12.5 per cent, in this 8-liter volume, a 10-ml. change in quantity of helium would result in a change of 12.5 volumes per cent or 1.56 per cent in the concentration. Since the error of analysis is of the same magnitude, determination of changes in concentration of helium after equilibrium between lung and spirometer has been reached cannot be expected to show this small magnitude reliably. As previously mentioned, methods of accurate absolute analysis for helium in the presence of other gases were not available. Proper investigation of this point remains for the future. Some helium must inevitably be absorbed during rebreathing, and if it were much more than 10 ml., we could have detected it with some accuracy. Therefore we have continued to subtract 110 ml. from the observed mid-capacity which is the amount attributable to a loss of 0 ml. of helium with an average mid-capacity of 2 liters. It is then to be remembered that all the mid-capacities by helium are made 110 ml. smaller by this rather arbitrary correction. In practice, 180 ml. were subtracted as the rounded total of the three corrections: mouthpiece, R.Q., and helium absorption. The mouthpiece volume correction is applied to the other calculations also, and the difference in inert gas between lung and spirometer due to R.Q. is also written into the equation $(Q.V.)$.

RESULTS OF COMPARISON WITH OTHER METHODS

The original Christie (2) mid-capacity method and the Lassen, Comar and Richards (3, 4) modification of the original Christie method are compared with the new helium method in ten normal subjects and eight patients with pronounced pulmonary emphysema in Table VI. Each determination was done in duplicate. There is less variation between duplicates by the helium method than in either of the other two methods, not only in normals but also in patients with emphysema. From the last two lines of Table VI it is seen that in the normal the volume determined with helium is virtually always smaller than the volume determined by the other two methods by an amount of approximately 200 ml. and 100 ml., respectively.

In this connection it should be recalled that the rather arbitrary correction for helium taken up by the body is of this same order of magnitude. We have no objective proof of the absorption of helium, although we know from purely physical considerations that some must take place.

It may be observed that differences between the original Christie and the corrected Christie, while fairly consistent in the normal subjects, are not at all so in those patients with emphysema, although according to the "oxygen storage" concept the difference should be more marked in this group. The original method gives values in normals consistently higher by about 1/10 liter. However, in the emphysematous patients no such consistency is observed and indeed the mean difference is in the opposite direction. The explanation of this inconsistency in the emphysematous patients is found in the variable relation of their initial and final alveolar air samples to outside air and to final spirometer nitrogen, respectively. It was our opinion that the corrected mid-capacity did not offer any advantage over the original method in pathological subjects despite the theoretical advantages described for it. In a personal communication the authors of the corrected method informed us that they now prefer their open method (9).

CONCLUSIONS

The principal advantage of this method of determining mid-capacity is the speed with which determinations may be carried out, together with evidence indicating a higher degree of reproducibility.

The method has been employed in the Cardio-Respiratory Laboratory of the University of Rochester for several years with very satisfactory results. The determination of mid-capacity is growing in clinical recognition, particularly in relation to the diagnosis of pulmonary emphysema. The facility with which the determination can be made will make possible broader application of this valuable test. It is evident that a number of steps might well be taken to simplify and further improve the method described. Particular attention ought to be devoted to reduction of spirometer circuit volume and increases in accuracy might be secured by employing higher concentrations of helium.

SUMMARY

1. A full description of a new method for the determination of the volume of the lung has been presented.

2. Graphic methods were employed for rapid solution of the calculations involved.

3. Data are presented to permit critical evaluation of the method as to reproducibility and as to comparison with two other methods.

4. The rapidity and accuracy of this new method recommend it for clinical application.

STUDIES ON HUMAN ALCAPTONURIA. EFFECT OF THIOURACIL, PARA-AMINOBENZOIC ACID AND DI-IODOTYROSINE ON EXCRETION OF HOMOGENTISIC ACID

By ABRAHAM G. WHITE,¹ JULIUS G. PARKER,² AND FRANK BLOCK

(From the Medical Division, Montefiore Hospital, New York City)

(Received for publication August 13, 1948)

The literature on alcaptonuria has been well summarized (1-6).

Paschke *et al.* (7) reported that thiouracil and para-aminobenzoic acid inhibited the *in vitro* conversion of tyrosine to melanin by tyrosinase, and White (8) found that thiouracil inhibited melanuria. Lerner and associates (9) noted that the tyrosinase of mouse melanoma is a copper protein whose activity can be inhibited by the addition of substances which combine with copper (phenylthiourea and others) and then restored by the addition of an excess of copper. Since homogentisic acid is an oxidative product of tyrosine, it seemed worthwhile to determine whether the production of homogentisic acid could be inhibited by thiouracil and para-aminobenzoic acid. When 3, 5, di-iodotyrosine is fed to rabbits, about 60% (Foster and Gutman [10]) is excreted as 3, 5, di-iodo-4-hydroxyphenyllactic acid. It, therefore, occurred to us that, since the number 5 carbon on the benzene ring is blocked by iodine, the alcaptonuric patient would not be able to utilize di-iodotyrosine as he would l-tyrosine to form homogentisic acid (2, 5, dihydroxyphenylacetic acid).³

Soderbergh (12) observed that the daily administration of 3.0 gm. of potassium iodide to an alcaptonuric decreased the urinary excretion of homogentisic acid by 2.0 gm. per day. This compound was administered to our patient in an attempt to influence similarly the excretion of homogentisic acid.

EXPERIMENTAL

The subject of our study was a 59-year-old white male, M.N., History No. 43082, who noted a blackish discolora-

tion of the ears 25 years ago, at which time it was observed that his urine became black on standing. Stiffness of almost all the joints occurred five years later.

Extensive laboratory examinations were essentially normal except for a blood uric acid of 6.8 mgm.% and the presence of homogentisic acid in the urine. The serological reactions for syphilis were negative.

Roentgenologic examinations were reported as follows. *Spine*: Marked hypertrophic changes were present. The intervertebral discs showed calcification, especially in the lumbar region. *Pelvis*: The right hip space was considerably narrowed and there was eburnation of the contiguous portions of the joint. *Knees*: There was calcification of the quadriceps tendons bilaterally. Hypertrophic changes were seen in both knee joints. *Legs*: Linear, irregular, and amorphous calcifications were seen in the soft tissues in the lower half of both legs. There was a mild osteoporosis of all bones. The ankles and feet showed no pathological changes. The changes described were considered characteristic of alcaptonuric ochronosis.

The genetic history of this patient is of interest. His parents were first cousins, neither of whom had alcaptonuria. The patient married a cousin who has no alcaptonuria. The presence of alcaptonuria and arthritis is indicated in Figure 1.

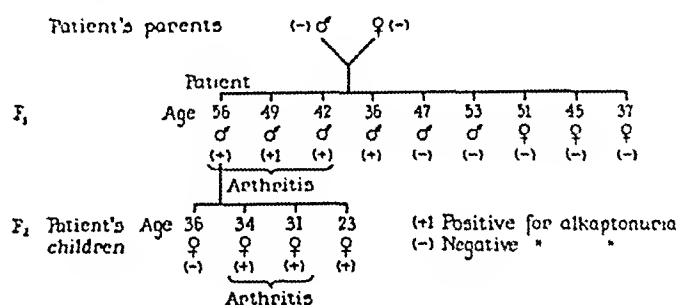

FIG. 1. GENETIC HISTORY OF ALCAPTONURIC PATIENT WHO WAS SUBJECT OF PRESENT STUDY

The effect of thiouracil and para-aminobenzoic acid on the urinary excretion of homogentisic acid was determined. In addition, the effects of potassium iodide, di-iodotyrosine and l-tyrosine were also observed.

Period 1: Control period of seven days. *Period 2:* Thiouracil 0.2 gm. t.i.d. was administered for 12 days. *Period 3:* Para-aminobenzoic acid was then given in doses of 4 gm., five times a day, with 30 c.c. of 5% NaHCO₃ accompanying each dose, for seven days. *Pe-*

* 48-hour urine collection and homogentisic acid output expressed per 24 hours.

riod 4: Control period of five days. *Period 5:* 2.0 gm. of potassium iodide per day were given orally as a 50% solution for three days. *Period 6:* 4.0 gm. of potassium iodide per day were given orally as a 50% solution for four days. *Period 7:* 8.0 gm. daily of di-iodotyrosine were given orally as a powder in four divided doses of 2.0 gm. each for five days. *Period 8:* 8.0 gm. daily of l-tyrosine were given orally as a powder in four divided doses of 2.0 gm. each for five days.

The daily diet during the entire period contained approximately 70 gm. protein and 1800 calories.

METHODS

Twenty-four-hour urine specimens were collected and preserved with approximately 10 c.c. concentrated HCl so that all specimens remained acid to congo red.

Homogentisic acid was determined quantitatively by the iodometric method as described by Lieb and Lanyar (13).

RESULTS AND DISCUSSION

Results are presented in Table I and Figure 2.

The average daily excretions of homogentisic acid in the control periods, 4.69 and 4.09 gm., agree well with the value of 4.65 gm. observed by Neuberger (5) in a patient receiving 60 gm. of protein daily.

Thiouracil and para-aminobenzoic acid did not inhibit the excretion of homogentisic acid since the average daily excretion was 4.53 gm. and 4.67 gm. for the respective periods. It, therefore, seems that the oxidative enzymes involved in the conversion of tyrosine to homogentisic acid are not similar to the tyrosinase concerned with the oxidation of tyrosine to melanin.

When 8.0 gm. of l-tyrosine were administered, the average daily excretion for this period was 7.98 gm. as compared with 4.09 gm. for the preceding control period. The difference, 3.89 gm., represents a conversion of 52.6%. Mittelbach (14) observed a low percentage of conversion to homogentisic acid when 15.0 gm. of l-tyrosine were given. This is in contrast with the 80% to 85% conversion of 3.0 gm. of l-phenylalanine observed by Neuberger (5).

Despite the large amounts (8.0 gm. daily) of 3, 5, di-iodotyrosine administered to our patient, the average daily excretion of homogentisic acid was 4.92, and this did not differ markedly from the control excretions. This would indicate an inability of the alcaptonuric to convert this compound to homogentisic acid.

Foster and Gutman (10) found that when 3, 5, di-iodotyrosine was fed to rabbits, about 60% was

FIG. 2. THE EXCRETION OF HOMOGENTISIC ACID IN GRAMS PER 24-HOUR PERIODS UNDER VARIOUS EXPERIMENTAL CONDITIONS

The amount of homogentisic acid is represented to the nearest tenth of a gram.

excreted as 3, 5, di-iodo-4-hydroxyphenyllactic acid. We did not expect this portion to be converted to homogentisic acid by our patient because the number 5 carbon was blocked by iodine. However, the remaining 40%, representing 3.2 gm. of the daily 8.0 gm. dose administered, might be available for conversion to homogentisic acid. This did not happen.

Soderbergh (12) observed that when an alcaptonuric patient was given 3.0 gm. of potassium iodide daily, the urinary output of homogentisic acid decreased to 6.50 gm. daily from a control level of 8.50 gm. We did not find any decrease in our patient.

CONCLUSIONS

1. An alcaptonuric patient on an approximately 70 gm. daily protein basal diet excreted a daily average of 4.69 gm. and 4.09 gm. of homogentisic acid during two control periods of seven days and five days respectively.

2. Thiouracil and para-aminobenzoic acid did not reduce the excretion of homogentisic acid.

3. 8.0 gm. daily of L-tyrosine yielded an average daily excretion of 7.98 gm. of homogentisic acid, which represented a conversion of 52.6%.

4. 8.0 gm. daily of 3, 5, di-iodotyrosine resulted in an average daily excretion of 4.92 gm. of homogentisic acid, essentially the control level.

5. Potassium iodide in doses of 2.0 gm. and 4.0 gm. daily did not decrease the urinary excretion of homogentisic acid.

6. The oxidative enzymes involved in the conversion of tyrosine to homogentisic acid differ in their lack of response to thiouracil from the tyrosinase which produces melanin.

ACKNOWLEDGMENT

We wish to extend our thanks for the advice and encouragement given by Dr. Louis Leiter, Chief of the Medical Division, Montefiore Hospital.

THE SIGNIFICANCE OF THE DIFFERENCE IN SYSTEMIC ARTERIAL AND VENOUS PLASMA CONCENTRATIONS IN RENAL CLEARANCE METHODS

By CLAUD BRUN, TAGE HILDEN, AND FLEMMING RAASCHOU

(From III Department of Internal Medicine, Kommunehospital, Copenhagen, Denmark)

(Received for publication July 12, 1948)

Diodrast clearance values reported in the literature have been calculated partly on constant and partly on rising or falling plasma concentrations. However, we have observed unexpectedly low clearance values on rapidly falling concentration, and as far as we know this phenomenon has not been reported before.

Published values of the diodrast clearance in normal subjects differ with the different techniques applied, and these differences may be explained in part, on the basis of our observations. By analyzing White, Findley and Edwards' (1) results we see that in the subjects where continuous infusion was applied, the average diodrast clearance was 517 ml./min., while in the subjects where falling plasma concentration after a single injection was used, the value was 410 ml./min. One of us, (Hilden [2], by application of an intravenous single injection, obtained an average clearance of 411 ml./min., whereas by subcutaneous injection, which gives a far more slowly falling plasma concentration, obtained a clearance of 613 ml./min. Goldring, Chasis, Ranges and Smith (3), who used continuous infusion, indicate the normal value to be 688 ml./min. Josephson (4) recently stated that he finds lower diodrast clearance values on the basis of spontaneously falling plasma concentrations than after a single intramuscular diodrast injection.

A few instances will be given first of the above phenomenon. Figure 1a shows the diodrast clearance at different plasma concentrations estimated on rising and falling concentration. Values calculated on falling plasma concentration at about 10 mgm. per cent cease to increase and in fact begin to decline. In comparison it may be seen that the values calculated on rising concentration at the same low level range from about 700 to about 1000 ml./min. The question of why the values vary so much during rising concentration will be discussed later. Similar results are plotted in

Figure 1b. From the moment the concentration begins to fall spontaneously the clearance declines at an increasing rate the lower the concentration. Here, too, the values are essentially higher when calculated on rising concentration. In Figure 1c the diodrast clearance values calculated on a falling curve have been compared with the diodrast clearance estimated on constant blood concentration; a marked difference is noted again. Figure 1d illustrates an experiment, in which a spontaneous fall in the plasma concentration was elicited over one hour and a half, and when the plasma concentration had fallen to 8 mgm. per cent, diodrast was infused intravenously, and the plasma concentration increased. The diodrast clearance increased from about 400 ml./min. to about 600 ml./min. at the same plasma concentration. Figure 1e shows an experiment beginning with an intravenous infusion of diodrast, which brought about a rapid rise in the plasma concentration. Then the infusion was discontinued with the result that the plasma concentration began to fall spontaneously. The diodrast clearances calculated on the rising curve were found to exceed those on the falling curve. The turn occurred at the moment the infusion was discontinued.

A total of 16 experiments were performed. Low clearance values on falling plasma concentration were unquestionable in 12 and in the remaining four the phenomenon was questionable or not present. The reason why the phenomenon may occasionally fail to occur will be mentioned later.

We shall now discuss the possibilities which we have considered in trying to explain the phenomenon.

a. In the above experiments *no* correction was made for delay time; by delay time we mean the time it takes for the urine to pass through the kidneys and the urinary tract from the moment of production until it has reached the bladder. The urine discharged from the bladder at a given point

FIG. 1 (a through e). DIODRAST CLEARANCE VALUES CALCULATED ON FALLING AND RISING PLASMA CONCENTRATIONS

Solid dots represent falling, and open circles rising concentrations.

of time is thus produced in the kidneys some five to 15 minutes previously (depending on, among other things, the urine volume). When working with rapidly varying plasma concentrations there may, accordingly, be a great difference between the concentration during which the urine is actually produced and that used in the clearance period. Clearance values determined on falling plasma concentration therefore will be calculated too high. Consequently, omitting correction for delay time cannot alone explain our observations.

b. If diodrast is deposited in the renal tissue for some time before being excreted the diodrast clearance will likewise be calculated too high, because at the high concentrations the excretion will lag somewhat behind the plasma curve.

c. Furthermore, the possibility might be conceived that, at rapidly falling plasma concentration, the erythrocytes were not able to give off their contents of diodrast during the rapid passage through the kidneys. This would result in a shift in favor of the erythrocytes of the normal equilibrium between the diodrast concentrations in blood cells and plasma. The erythrocytes might be conceived to give off diodrast to the plasma after the blood sample had been taken, and the diodrast concentration in plasma accordingly be analyzed as higher than it had been when the blood passed through the kidneys. To elucidate this fact, we compared the diodrast concentrations in blood plasma centrifuged off immediately after withdrawal of blood, and plasma which had been left standing with erythrocytes for an hour after withdrawal. This analysis showed that no diodrast is given off from the blood cells, and that accordingly no such process can explain the phenomenon.

d. Differences in the binding of diodrast to the plasma protein substances, at falling and rising plasma concentration, might likewise be conceived to be responsible for a difference in the plasma excretion of diodrast in the kidneys. This seems rather unlikely, however, since the dissociation of the diodrast-protein complex is known to take place very quickly; the blood is, at least at plasma concentrations below that at which the clearance is self-depressed, almost completely cleared of diodrast by a single passage through the kidneys.

Thus, none of the four possibilities mentioned above appear to explain the low diodrast clearance

values calculated on falling plasma concentrations. However, we believe we have found an explanation in another possibility; the diodrast concentration in arterial blood may differ considerably from that in venous blood, when the plasma concentration is changing quickly.

e. The distribution of diodrast in the circulation, *while the concentration falls*, must be supposed to occur in the following way: the renal venous blood, which is almost or completely free of diodrast, is led to the right half of the heart, where it is mixed with diodrast-containing venous blood from the extrarenal part of the organism. The concentration in the mixture will be identical with that in the arterial blood. It appears, therefore, that the diodrast concentration in arterial blood must be lower than that in the venous blood from the arm generally applied for analysis. Since the clearance (UV/P) ought to be calculated on the basis of the concentration of arterial blood from which diodrast is actually excreted by the kidneys, then the clearance values will be calculated too low when the venous blood concentration is used in the formula.

To this hypothesis the objection might be raised that the above difference between the concentrations in arterial and venous blood always must be present, since the renal venous blood in normal individuals always must represent an afflux poor in diodrast to the heart. If one, however, maintains a *constant* diodrast plasma concentration by continuous infusion, the concentrations in arterial and in mixed venous blood will be identical; the concentration is maintained by supplying diodrast to the venous blood at a rate equal to that at which it is being excreted through the kidneys.

During rising plasma concentration the arterial blood concentration should accordingly be higher than the peripheral venous blood, because the mixed venous blood is being fortified at a rate greater than the rate of excretion. The mixed venous blood (and the arterial blood) will have, therefore, a higher concentration than peripheral venous blood. The arteriovenous difference will depend mainly on the relative rates of loss and infusion.

On the basis of these considerations we have determined the relative concentrations in arterial and venous blood under conditions of rising, falling and constant diodrast concentration.

FIG. 2 (a through f). DIODRAST PLASMA CONCENTRATIONS IN ARTERIAL AND VENOUS BLOOD ON RISING AND FALLING PLASMA CONCENTRATIONS

Solid dots represent concentrations in arterial, and open circles concentrations in venous blood.

TECHNIQUE

Venous and arterial blood samples were taken every ten minutes. Blood was collected from a retention cannula in the median cubital vein, brachial artery or femoral artery. Clotting was prevented in the venous cannula by constant, slow infusion of a dilute heparin-saline solution.

Urine was collected by catheter and the bladder was washed twice with 50 ml. of water plus air after each discharge.

Diodrast was analyzed by Bak, Brun and Raaschou's (5) modification of White and Rolf's (6, 7) method. Inulin was analyzed by Brun's (8) modification of Corcoran and Page's (9) and Miller, Alving and Rubin's (10) method.

Procedure of experiments. The subjects used in this study showed no evidence of cardiovascular-renal disease and were afebrile.

The experiments were carried out in three different ways. Generally, a rather rapid rise in the plasma concentration was first obtained by the intravenous infusion of diodrast solution. The infusion was discontinued when the concentration had reached a sufficiently high level, and the concentration was left to fall spontaneously. In other subjects a large intravenous single injection brought about a high diodrast concentration which was allowed to fall spontaneously.

RESULTS OF EXPERIMENTS

Six experiments were made with simultaneous determination of the diodrast level in arterial and venous blood on rising and falling concentration. Figure 2 illustrates the blood curves plotted for all six experiments. Table I shows the results from two of the experiments (P. L. and M.) in a more detailed form.

During falling plasma concentration the diodrast level is higher in venous blood than in simultaneous arterial blood, whereas the reverse is the case during rising plasma concentration.

Table II shows the average percentage differences between diodrast and inulin concentrations in arterial and venous blood (expressed in per cent of the arterial blood concentration) during spontaneously falling concentrations. In the case of diodrast the differences have been calculated only for the concentrations below the self-depression limit. With regard to diodrast the average difference for all six experiments was 29 per cent. This figure corresponds approximately to what might be expected from theoretical calculations. The arteriovenous difference in concentration will depend partly on the diodrast extraction in the kidneys and partly on the ratio between the "renal"

TABLE II

Comparison of diodrast and inulin concentration differences (in per cent) in arterial and systemic venous blood during spontaneously falling concentrations

Subject	Diodrast	Inulin
	per cent	per cent
H. A. (male)	28	5.8
P. J. (male)	26	7.0
M. (male)	31.3	8.0
A. (male)	10.9	
P. L. (male)	52.0	8.7
Average	28.7	7.4

The values are obtained using the following formula:

$$\frac{P_{DV} - P_{DA}}{P_{DA}} \cdot 100 \quad \frac{P_{INV} - P_{INA}}{P_{INA}} \cdot 100$$

in which P_{DA} and P_{INA} are the arterial plasma concentrations of diodrast and inulin and P_{DV} and P_{INV} are the venous plasma concentrations of diodrast and inulin.

and the "extrarenal" minute volume. Starting from a level below the self-depression limit, where the renal venous blood is almost completely cleared of diodrast, and supposing that one-fifth of the minute volume of the heart passes through the kidneys, we may set up the following equation from which the ratio of arterial concentration to venous blood concentration may be calculated:

$$V \times P_{DA} = 1/5V \times 0 + 4/5V \times P_{DV} \\ P_{DV} = 5/4V \times P_{DA}$$

P_{DA} and P_{DV} are the diodrast concentrations in arterial and venous blood, and V the cardiac output.

In the case of inulin, the renal venous blood will be cleared of only about one-fifth of the quantity present in the arterial blood. Hence the equation for inulin is as follows:

$$V \times P_{INA} = 1/25V \times 0 + 24/25V \times P_{INV} \\ P_{INV} = 24/25V \times P_{INA}$$

where P_{INA} and P_{INV} indicate the inulin concentrations in arterial and venous blood.

In the case of inulin, too, the difference found (7.4 per cent Table II) corresponds fairly closely to what might have been expected.

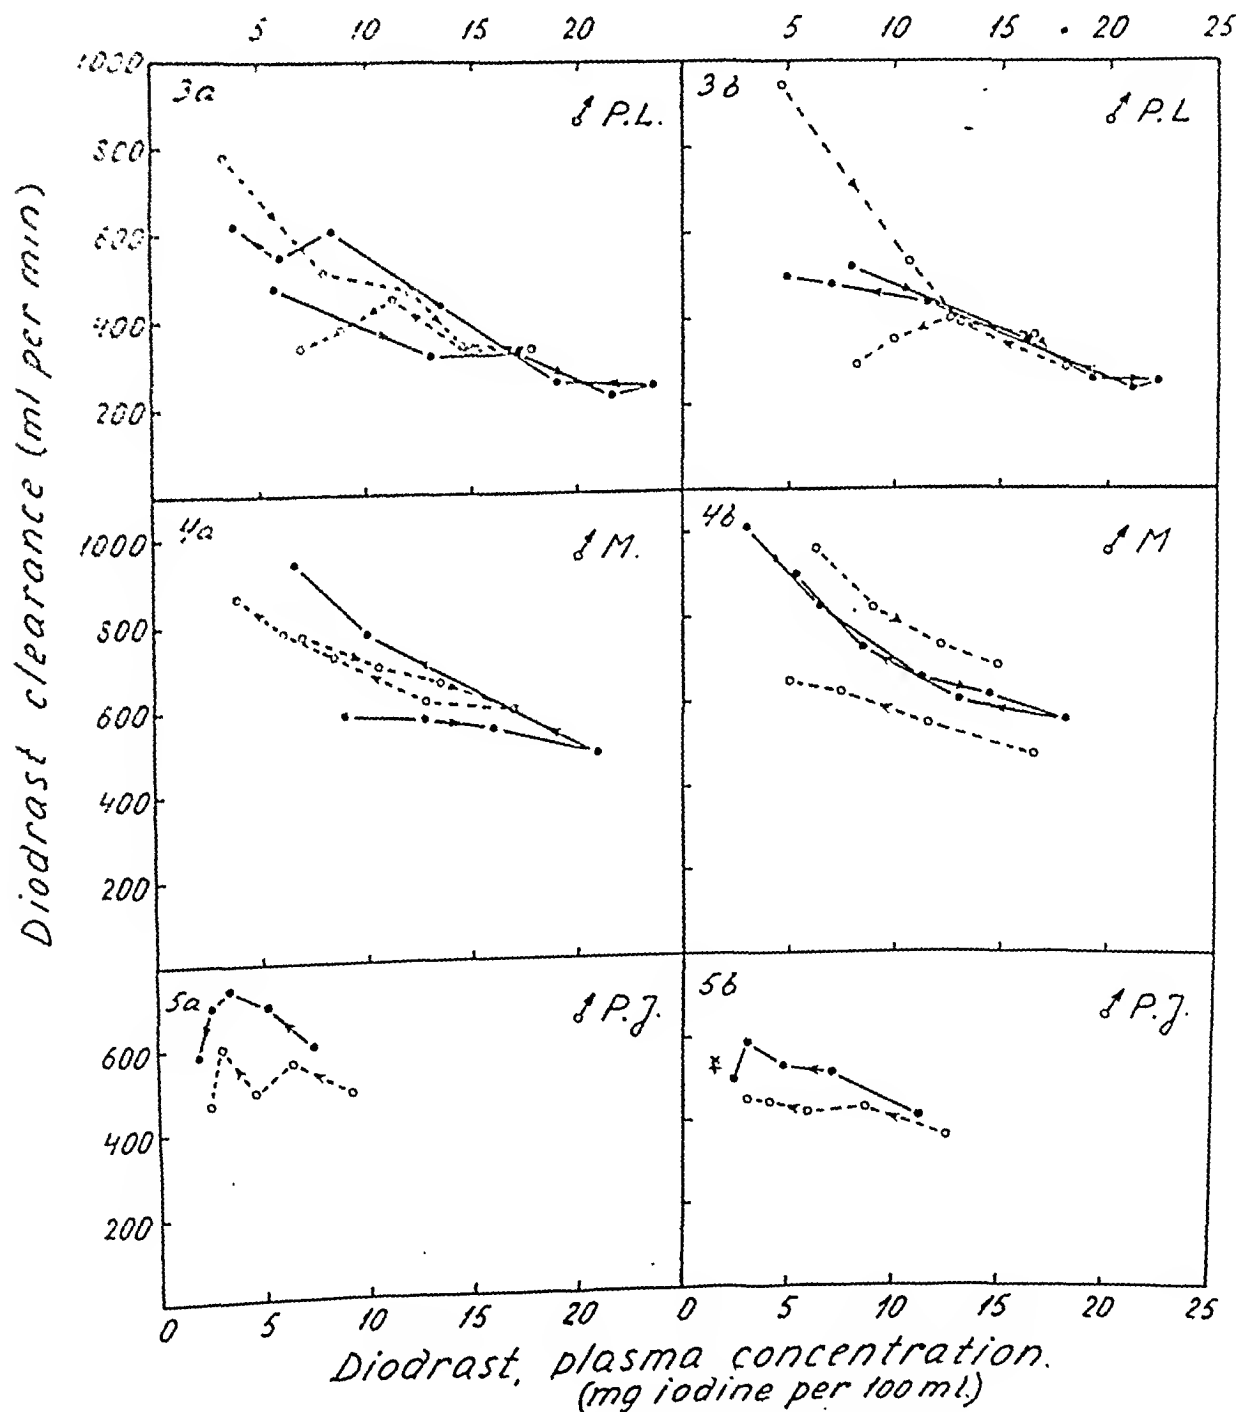

These calculations are approximate, of course, because we do not know the exact ratio between the cardiac output and the renal blood flow. Moreover, we cannot *a priori* be certain that the deposition of diodrast is uniform in all tissues. On the contrary, investigations by Lengemann (11) seem to show that the largest amounts of diodrast are deposited in liver and skin. The blood from the median cubital vein is cutaneous venous blood and

it may be particularly rich in diodrast on falling plasma concentration.

During rising plasma concentration the level in the arterial blood is, as mentioned above, higher than in the corresponding venous blood, partly because a certain amount of diodrast is deposited in the tissues and partly because of the variations in

the distribution of diodrast in the blood. The rate of infusion is the factor determining the arterio-venous concentration difference.

We shall now report the results arrived at by calculating the diodrast clearance on the basis of arterial blood concentration and venous blood concentration, respectively. The diodrast clearance

FIGS. 3-5. DIODRAST CLEARANCE VALUES CALCULATED ON THE BASIS OF ARTERIAL AND VENOUS PLASMA CONCENTRATIONS

Figs. 3a, 4a, and 5a show uncorrected clearance values, and Figs. 3b, 4b, and 5b show clearance values which are corrected for delay time. Solid dots represent arterial, and open circles venous plasma concentrations.

values refer partly to Table I (P. L. and M.), and partly to Figures 3, 4 and 5 (P. L., M., and P. J.).

By using the arterial and venous concentrations and without allowing for delay time we arrive at the results indicated in Figures 3a, 4a, and 5a.

In Figure 3a (P. L.), the "venous clearance" values are seen to be high on rising and low on falling blood concentration, while the "arterial clearances" are low on rising and high on falling blood concentration. On the other hand, it appears that the "venous clearance" (Figure 4a) may be identical on rising and falling blood concentrations, whereas the "arterial clearance" is low on rising and high on falling blood concentration. Finally, it appears from Figure 5a that the "arterial clear-

lay time in normal individuals for different urine volumes. In the present article it will only be pointed out that the delay time must be supposed to be longer than it was previously thought to be (three minutes), (Goldring, Chasis, Ranges and Smith [3]). For urine volumes like those dealt with in our experiments ($1\frac{1}{2}$ to 5 ml. per min.) the delay time is between five and eight minutes.

With allowance for these facts we have calculated the diodrast clearance values indicated in Figures 3b, 4b and 5b, as well as in Tables I and II, which show that the "arterial clearance" values are identical during rising and falling blood concentrations, whereas the "venous clearance" values are low on falling and high on rising blood concentration. It appears from Figure 5b that, after correction for delay time, the "arterial diodrast clearance" values calculated during falling blood concentration are found to be comparable with the diodrast clearance calculated on the basis of a constant plasma concentration curve.

Finally some experiments were made in order to investigate the arterial and the venous plasma concentrations of diodrast using the constant intravenous infusion method. The arterial and the venous plasma concentrations are seen to differ very little (Figure 6). The clearance values calculated on the basis of the arterial plasma concentration were practically identical with those calculated on the venous plasma concentration.

FIG. 6 (a through c). DIODRAST PLASMA CONCENTRATION IN ARTERIAL AND VENOUS BLOOD DURING A CONSTANT INTRAVENOUS INFUSION.

Solid dots represent concentrations in arterial, and open circles concentrations in venous blood.

ance" values are higher during spontaneously falling blood concentration than the "venous clearance." That the diodrast clearance has been calculated on the basis of concentrations above the self-depression limit is naturally of no importance in these subjects, where it was the question of comparing the "arterial" and the "venous" clearance values calculated on simultaneous plasma concentrations, and not of estimating the absolute clearance values.

However, we feel that allowance should be made for delay time in the calculation of the diodrast clearance. In a subsequent article (12) we will publish the results of experiments dealing with de-

DISCUSSION

It appears from the results of the above experiments that the "venous diodrast clearance" values calculated during rapidly falling or rising plasma concentrations are either too low or too high. The "arterial diodrast clearance," on the other hand, presents identical and correct values under the same experimental conditions *provided that allowance is made for delay time*.

We may, therefore, for the present conclude that the cause has been found for the error in the diodrast clearance, when it is calculated using venous blood analyses and falling plasma concentration; the error is due to the difference between the diodrast concentrations in arterial and venous blood.

Foa and Foa (13) calculated the diodrast clearance on the basis of a falling plasma concentration

curve and venous blood analyses, a procedure which, according to the above observations, we cannot recommend. That these writers found the average normal value to be as high as 566 ml./min. is no doubt due to the fact that they made no allowance for delay time. This may in some measure eliminate the error made in diodrast clearance calculation based on rapidly rising and falling plasma concentrations, and may offer an explanation of the fact that in some cases we did not observe low clearance values on falling concentrations.

It has previously been mentioned that strikingly high and irregular diodrast clearance values may be observed within the first part of an infusion period (cf. Figures 1a and 1b), as well as at a later stage of the experiment, whenever there is a great increase in the infusion rate. This may be owing in part to the fact that the tissues are not saturated with diodrast, and consequently, the percentage difference between the diodrast concentrations in arterial and venous blood is large. The plasma concentrations, therefore, used in the clearance calculation are far too low when venous blood analyses are used. Another cause may be the fact that at the beginning of some of our experiments the infusion was irregular, so that sudden and relatively great changes might have occurred in the diodrast concentration in arterial blood without these fluctuations necessarily being reflected to the same extent in the venous blood. Finally the possibility cannot be omitted that actual variations in the renal plasma flow underlie these high and irregular clearance values. ✓

CONCLUSIONS

1. Diodrast clearance values obtained during rapidly falling plasma concentration are erroneously low. This error is due to the fact that significant differences in diodrast concentrations between arterial and systemic venous blood occur during rapidly rising and falling plasma concentrations. Therefore the customary use of peripheral plasma concentration in calculations of the diodrast clearance can lead to large errors.

2. If arterial plasma concentration is used and if correction is made for delay time the diodrast

clearance is independent of rate of change in the plasma concentration.

3. If a constant intravenous infusion is used, the clearance calculation using venous plasma concentration is permissible.

STUDIES ON PAIN: MEASUREMENTS OF PAIN INTENSITY IN CHILDBIRTH¹

BY JAMES D. HARDY AND CARL T. JAVERT

(From the Russell Sage Institute of Pathology, The New York Hospital and the Departments of Physiology, Obstetrics and Gynecology, Cornell University Medical College, New York City)

(Received for publication July 22, 1948)

It is a common observation that patients differ widely in their reaction to childbirth, some women giving evidence of great distress and others maintaining a high degree of equanimity throughout labor. These variations in reaction have led obstetricians to question the existence of pain in certain patients (1), except for the sensations accompanying the surgical procedures often required for the delivery of the baby. In the absence of a quantitative method for measurement of pain intensity, the reaction of the patient has been the principal index of the severity of labor pains.

The introduction of dolorimetry, a laboratory method of measuring painfulness, by Hardy, Wolff and Goodell (2, 3), has made it possible to obtain reliable estimates of spontaneous and experimentally induced pain intensity. This method provides a scale based on the ability of an individual to discriminate differences in the intensities of pain. The technique consists essentially of comparing the intensity of a spontaneous pain with that induced on the skin of the subject by thermal radiation. No clinical application of this method has yet been made, and in applying it to the study of the pain experienced during labor, it was hoped that the patient could make reproducible comparisons of the labor pains with those evoked by the thermal stimulus on the skin. If this proved possible, the intensity of the painful sensations experienced by a patient in the various stages of labor and by different patients, could be compared on a common basis. This would provide a convenient method for the evaluation of the effectiveness and mode of action of analgesic agents administered for the relief of pain during labor.

It is the object of this report to present experimental data on pain intensity, obtained from a study of 13 women in the various stages of labor

before the administration of any analgesic or anesthetic agent.

METHOD

Thirteen normal young women without obvious medical or obstetrical complications cooperated as subjects in these experiments. There were ten primiparas and three multiparas. Nine were private patients who had a definite interest in the investigation as they were either former nurses or wives of physicians or professional men. Special urging was unnecessary to persuade these patients to participate in this study, as either curiosity or desire to be of service caused them to volunteer readily. All patients had one motive in common, namely, to withstand any reasonable discomfort if it would help ease the suffering of future patients. The matter was, of course, discussed with the husband and in instances in which the patient was the wife of a physician the husband remained in the room while the study progressed. In two instances the pain studies were discontinued in the latter part of the first stage of labor at the patients' request. At first private patients were deemed most suitable for this study as it was not clear that discriminating differences in intensity of pain would be a simple matter during the course of labor. Since these patients had no difficulty in making the necessary comparisons, four clinic patients were subsequently included in the study.

Prior to hospital admission in labor, all of the private patients had been given preliminary instruction in the thermal radiation technique of pain threshold measurement (4). The operation of the equipment was explained to them, and they were introduced to the several persons involved in the study who would be present during the investigation. As the authors and a technician remained with the patient during the entire period of observation, it was felt desirable that rapport be established between the patient and the experimental team.

During the first laboratory interview the skin of the dorsum of the right hand was blackened with India ink in four areas, and the pain threshold measured on these test surfaces. The pain threshold was measured by first exposing the blackened skin for three seconds to an intensity of thermal radiation slightly above the pain threshold so that a distinct pain was felt. Then, beginning with a stimulus well below the pain threshold, the radiation intensity was increased through successive exposures until the patient reported a barely perceptible prick at the end of the exposure. This intensity was

¹ This work was supported in part by funds from the Office of Naval Research of the United States Navy.

taken as the pain threshold. It is of the greatest importance that different areas of skin be stimulated in each exposure, and that as few stimuli as possible be given to locate accurately the threshold. An average of four stimuli was usually sufficient to determine the pain threshold within plus-minus ten millicalories per second per square centimeter. None of the patients studied had the slightest difficulty in recognizing the pain threshold.

During this period of instruction the difference in intensity of two pains was demonstrated by exposing the patient to a stimulus evoking a two-dol² pain and then to one evoking a four-dol pain. This was done to impress upon the patient the importance of the intensity aspect of pain as contrasted with its quality and duration, since the experimental pain ostensibly differed from the labor pain in these respects. Most of the patients commented upon the fact that the sensation from the uterus would be different in quality, duration and locale, and, therefore, expressed some doubt as to the possibility of equating the two sensations in terms of intensity. These apprehensions were not borne out by experience as only two of the patients had difficulty in making comparisons, and in these instances the degree of cooperation was not sufficient to continue the observations through the first stage of labor.

The use of the word "pain" in connection with the uterine contraction was avoided in discussing the subject with the patients, and "intensity of contraction" was the descriptive term employed. It was hoped in this way to avoid suggesting to the patient that her labor would be painful.

During labor the technique for measuring pain intensity was as follows: Immediately following a contraction the patient was given a three-second exposure to the thermal stimulus. She made a report as to whether or not the sensation on the back of her hand was more or less intense than that experienced from the uterine contraction. Depending upon this report the intensity of the stimulus was increased or decreased and the test repeated in order to "bracket" the uterine sensation. By having two stimuli, one lower and one higher than the spontaneous sensation, it was possible to find quickly the stimulus which the patient reported to be approximately of the same intensity as her labor pain. Usually three or four stimuli were enough to locate the balance point between the sensation from the uterus and that from the pain apparatus, but if more stimuli were required a rest period of about ten minutes was allowed before resuming tests. Care was taken throughout not to overstimulate any area of blackened skin and thereby produce local hyperalgesia.

It was repeatedly observed that the intensity report was the same whether the comparison of sensations was made at the height of a contraction or in the interval between contractions. As there was more time available between contractions comparisons were usually made then, adjusting the thermal stimulus to produce a sensation equivalent

² "Dol" is the term used to denote the unit of painfulness, and has a value of approximately one-tenth the intensity of the maximal pain.

in intensity to that evoked by the previous contraction. Two measurements were made and if the reports agreed within one dol they were averaged and used as the point to be plotted. Single test reports were used only at the highest pain intensities, because of tissue damage resulting from the strong thermal stimuli. Large variations in reports of intensity (three to five dols) occurred when the patient was distracted or not cooperating, and were observed in both patients who requested that the study be discontinued. This possibility had been anticipated since erratic reporting had been observed in a previous study of medical students (3). In spite of the clinical procedures necessarily carried out during the course of the pain study, the fatigue of the patient, and other disturbing circumstances that could not be controlled or eliminated, distraction resulting in erratic estimates was not an important factor. Reproducibility of the measurements within plus-minus one dol was taken to be the criterion of the excellence of the data.

Continued emphasis was placed during labor upon the *intensity* of the sensation as distinct from its quality and duration, because the patients frequently stated that the thermal pain was not "comparable" to the labor pain. The difference between the experimental pain and the labor pain may have caused some difficulty in making accurate comparisons. However, repeated comparisons during labor showed only variations of approximately plus-minus one dol, and as the limit of discrimination is plus-minus one-half dol this shows that the patients were making satisfactory appraisals.

It is important to keep in mind that as the severity of labor pain increases, thermal stimuli of correspondingly higher intensity must be administered and tissue damage will be produced when the comparisons extend beyond eight dols.

Pain threshold measurements were made throughout the entire period of study, in the intervals between contractions. It has been previously shown that an existing pain will cause an elevation of the pain threshold elsewhere in the body (4), and for this reason pain threshold measurements were not made during a contraction.

As soon as the patients were admitted to the hospital they were placed in a private labor room for study. One of the experimental team remained with the patient at all times, and pain tests were made every half hour or when there was any change in the patient's obstetrical status. The majority of the measurements were made in the first stage of labor, although two patients were observed in the second stage, and two in the fourth stage (5). No measurements were made in the third stage. None of the patients had had any analgesic or anesthetic during the time they were studied, although subsequent to the pain studies nine had analgesics and 11 had anesthetics for the delivery. If at any time during the study a patient requested an analgesic it was administered and the pain studies were terminated. This accounts for the fact that most of the patients were studied in the early and middle parts of the first stage of labor.

Measurements were made of the frequency and duration of uterine contractions by manual palpation of the

subject's abdomen. Cervical dilatation was estimated by rectal examination and in some instances confirmed by sterile vaginal examination.

In four patients records were made of the uterine contractions by means of a pneumograph strapped to the abdomen. It was not anticipated that the excursions of the pneumographic needle would be proportional to the intensity of the uterine contraction, but the duration of contraction and the interval between contractions could be more accurately determined in this way than by manual palpation of the abdomen. The patient was given a signal magnet key to press during the time she felt pain, as it was desirable to know whether or not the pain outlasted the contraction. The patient was also asked to give an estimate of the intensity of her pain each five seconds during the contraction. The reports were made in terms of fractions of the intensity of a recently measured uterine pain. This type of procedure for estimating pain intensity had been proved successful in the study of headache and other pains (6, 7).

In the course of all studies careful notes were kept as to the patients' reactions, such as crying, complaining, sweating and degree of alertness and cooperation in the pain studies. Such notes were used to arrive at an estimate of the patient's reaction to her pain.

RESULTS

Figure 1 shows the results obtained on the first patient studied. This individual was a primipara, a professional woman of high intelligence, who wished to experience labor without analgesia, because of her interest in Read's publications on natural childbirth. Studies were begun five hours after onset of the first pains, at which time labor was still mild, and the pain intensity averaged approximately three dols. The cervix was three centimeters dilated; uterine contractions occurred at five-minute intervals and lasted approximately 30 seconds. During the next five hours, as the cervix dilated gradually, the pain increased steadily, reaching an intensity of eight dols, and the contraction interval decreased to one minute.

The subject was calm throughout the course of her labor except for obvious tenseness. However, after the pain had reached eight dols (a severe pain) she asked for an analgesic. This was ad-

Ordinates: Dots represent duration of contraction in seconds; circles—contraction interval in minutes; triangles—cervical dilatation in centimeters; and crosses—pain intensity in dols.

ministered in the form of nitrous oxide during the second stage.

The second patient was a multipara who had had an unhappy obstetrical history characterized by six spontaneous abortions and only one living child. When the study began her pains were moderately severe, the cervix was closed and the contraction interval was about four minutes. In the next two hours the pain rose very rapidly to the extreme range above nine dols, as shown in Figure 2. The cervix dilated rapidly, and the contraction interval shortened in proportion. Two measurements were made on this patient during the second stage of labor, although the patient had been repeatedly warned of the danger of blistering. Yet she wished to cooperate fully as an expression of her gratitude in having a term pregnancy and insisted on having the tests made. A pain intensity of $10\frac{1}{2}$ dols was measured. This is the most intense pain which can be experienced. Increasing the intensity of the thermal radiation can cause

no further increase in pain perception (2). Second degree burns were inflicted upon the hands of this patient by the four tests made at levels higher than nine dols. Delivery was accomplished under general anesthesia.

Figure 3 shows a composite study of the 13 patients. As each determination represents not less than eight tests for pain intensity, the 55 measurements are the result of over 400 test readings. These 55 measurements represent an average of about four per patient during the various stages of labor. Since the first stage of labor had a variable duration for each patient, the time scale is expressed in quarters in order to obtain a common basis for comparison. It will be observed that there was a gradual increase in pain intensity as delivery approached, at which time pain reached nine and even $10\frac{1}{2}$ dols. The dashed line in the figure represents an approximate average of observed values in the first and second stages of labor. In the case of subject H, whose values lie

FIG. 2. PAIN CHART OF MRS. A
Symbols the same as in Figure 1.

FIG. 3. PLOT OF 55 DETERMINATIONS OF PAIN INTENSITY ON 13 PATIENTS DURING FIRST, SECOND AND FOURTH STAGES OF LABOR

Time scale of first stage expressed in quarters of its total duration.

quite far above the dashed line, it is to be remarked that the progress of her pains was parallel to the average line, but subsequent to the last determination shown she received a considerable amount of an analgesic which may have prolonged her labor.

The intensity of the after pains was measured in only two patients who had received no analgesia in labor and no anesthesia for delivery. These pains were moderate, three to five dols, a half hour after delivery, and decreased to threshold levels two hours later.

Figure 4 shows typical uterine contractions as recorded on the pneumograph. "A" is the recorded curve of contraction; line "B" shows the duration of pain as recorded by the patient when she pressed the key of the signal magnet; and curve "C" is the estimated intensity of pain. The first contraction was recorded in the early part of the first stage of labor, the second during the middle of the first stage, and the third curve during the second stage. It will be seen that the pain in each case was of shorter duration than the contraction, which is in contrast with the findings in

dysmenorrhea. Chassar Moir (8) has reported that in cases of dysmenorrhea the pain outlasts the uterine contraction and from this observation he suggested that the pain of dysmenorrhea might be attributed to hypoxia in the uterine muscle. It will be noted, too, that the stronger pains represent a greater proportion of the time of contraction than do the weaker pains, the range being from 15 per cent to 95 per cent of the total contraction time, depending upon the intensity of the contraction. This indicates that for weak contractions the pain threshold is reached more slowly than for stronger contractions.

The duration of contractions varied considerably from time to time in the same patient in various stages of labor, and showed no tendency to increase as delivery approached. This is in agreement with the observations of Murphy (9) who reports a decrease in average contraction time as labor advances.

DISCUSSION

The first questions to be answered were whether or not the method of dolorimetry was applicable to

the measurement of pain intensity in labor, and, if so, what were the limitations of the method.

The more than 400 trial tests resulting in 55 successful measurements of pain intensity on 13 patients establishes the method as a practical one for this type of investigation. However, this study does not attempt to be a complete survey since it does not include examples of the many types of labor and dystocia that may be found in the obstetrician's practice. Measurements can be made easily on any patient who can cooperate. The effects of distraction and lack of cooperation can be recognized by the large and rapid variations in estimates of pain intensity. Although the data are obtained from subjective comparisons of pain intensity, the test instrument affords an evaluation of the patient's report over which the patient has no control.

The most important limitation of the method is the inflicting of burns when high pain intensities are measured. A second limitation is that measurements cannot be made in the face of distraction and lack of cooperation. The patient must be willing and able to make comparisons of her painful sensations with those induced by thermal stimuli.

1. Pain intensity

In every patient studied the pain intensity increased as the labor progressed (Figure 3). Although few observations are available during the first quarter of the first stage of labor it can be safely assumed that these pains were of a mild intensity, averaging probably not more than one or two dols. Pain in the second quarter of the first stage was moderate, averaging between three and five dols. During the third quarter the pain of most patients averaged between five and seven dols, which is a severe pain. It was at this point that most patients asked for relief. In the last quarter, the pain was between seven and ten dols. The second stage of labor was characterized by the most severe pains, $10\frac{1}{2}$ dols, accompanying the "bearing down." After delivery the pains observed in the fourth stage of labor were again of mild intensity.

An approximate correlation could be made between the intensity of the pain and the extent of the cervical dilatation. Thus, when the patient was experiencing pain of ten dols it was found that the cervix was fully dilated, and if the pain was of one or two dols' intensity the cervix was observed

FIG. 5. DIAGRAM OF THE PAIN PATHWAYS OF IMPORTANCE IN CHILDBIRTH

First stage of labor: Visceral afferents arising in plexi enervating uterus, cervix and vagina; pathway: Frankenhouser's ganglion (F.G.) into hypogastric plexi (I.H.P., M.H.P., and S.H.P.) thence through the celiac plexus (C.P.), the superior and inferior mesenteric and aortic plexi (S.M.P., I.M.P., and A.P.) and the sacral plexus (S.P.) into spinal outflow from T6 to S4.

Second stage of labor: Visceral afferents plus somatic afferents via the pudendal nerve.

to be almost closed. However, a much more quantitative relationship appeared to exist between the pain intensity and the interval between contractions.

The relationship observed between the contraction interval and the intensity of pain provides a simple method for computing the pain from measurements of this interval. Thus,

Dols of pain = $10.5 - 1.5 \times \text{contraction interval in minutes.}$

This formula may not apply generally, of course, to all cases, although it has been observed to be valid in our series of patients without analgesia.

2. Character and origin of pain

During the early part of the first stage of labor the pain was of short duration and of a dull aching

quality, and was associated with a uterine contraction of relatively low intensity (see Figure 4, Curve 1). The visceral structures involved in producing this pain are deep and noxious impulses probably reach the central nervous system via the sympathetic and parasympathetic afferents (10) as diagrammed in Figure 5. As the cervix dilated and the uterine contractions became stronger the pain assumed a sharper quality. It had been noticed in other studies of pain intensity that bright, burning pain and dull, aching pain have a tendency to become similar. That is, a burning pain had an aching quality and an aching pain became sharp (3). This was also true of labor pains.

The ceiling pain was not reached until the beginning of the second stage at which time the somatic perineal structures were involved. These

superficial structures are innervated chiefly by the pudendal nerve (10), as shown in Figure 5, and the most intense pains are caused by the stretching and tearing of these tissues, with accompanying stimulation of the perineal reflex and considerable increase in intrauterine pressure (10). Curve 3, Figure 4, shows a recording of the onset of the reflex which is apparently inhibited periodically, possibly by the intense pain. Superimposed on the low uterine component of the pressure wave were spikes of great pressure from the perineal reflex. The duration of the pain at this time was almost as long as the contraction.

Figure 6 shows a plot of the pain intensity in dols against the uterine contraction in minutes. The connection between the contraction interval and uterine effort has been established by the tocographic measurements of Murphy (9) and others (11), and while it cannot be assumed that the tocographic measurements are necessarily representative of intrauterine pressure, they appar-

ently do represent the uterine hardness and thereby offer a measure of the uterine spasm (12). The uterine pressure in millimeters as estimated from Murphy's work is plotted to the right in Figure 6, and it can be seen that the pain intensity in dols is also proportional to the uterine pressure in millimeters, measured on Murphy's tocograph. This evidence, as well as the clinical observation that dilatation of the cervical canal causes severe pain, supports the conclusion that the pain in the first stage of labor is largely due to the distention of the internal os and the cervical canal as a result of the increased intrauterine pressure caused by uterine contractions.

3. Reactions to pain

During the early hours of labor there were generally few complaints and the patients were alert and interested in the study. There was no sweating. Two patients did not fall into this pattern. Mrs. O soon began to show hostility to the entire experimental team in spite of expressing many

FIG. 6. PLOT OF ESTIMATES OF PAIN INTENSITY (DOLS) AGAINST LENGTH OF INTERVAL BETWEEN CONTRACTIONS (MINUTES)

Ordinate at the right of diagram represents Murphy's tocographic measurements of uterine pressure.

times prior to admission her desire to participate in the study. Cajoling and persistence made it possible to carry on the study and in spite of this difficulty the pain measurements obtained were in the range of those for the more cooperative patients. Mrs. U cried and complained with vigor from the outset although her pain measurements indicated only two to four dols. This patient succeeded in becoming so excited that no further observations could be made in her case.

Late in the first stage 11 of the 13 patients were sweating and crying with each contraction, and were cooperating only with difficulty. Pain was severe at this time, seven to ten dols. One patient, Mrs. A (see Figure 2), gave little evidence of her pain. As a multipara her labor was short and this may account for her restraint in the face of pains measured at eight to ten dols. Fatigue was as important as pain intensity in bringing about a breakdown in the restraint most of the patients maintained over their actions. Thus, in her short labor, Mrs. A gave less visible evidence of pain at eight dols than did the other patients with longer labors at four dols.

The evidence of this study is that the reactions of the patient depended partly on the pain and to a greater extent on fatigue, anxiety, and, in some cases, hostility, whereas the pain intensity as measured was related to the uterine activity and dilatation of the cervical and perineal tissues. It seems important, therefore, to make a clear distinction between the intensity of the pain perceived by the patient and visible evidences of reaction to pain, such as complaining, groaning and crying out. These findings bear out the clinical impression regarding the psychological factors affecting the behavior of patients in labor. However, by measuring the intensity of the pain it is now possible to evaluate more fully the effects of pre-conditioning (as in "natural childbirth") and reassurance, as well as the action of analgesia upon pain sensation in the obstetrical patient. Further studies are planned to include an appraisal of suggestion and hypnosis.

SUMMARY AND CONCLUSIONS

1. Four hundred test readings, resulting in 55 measurements of pain intensity, were made on 13 patients during the first, second and fourth stages of labor without analgesia. The measurements

were made by comparison of the labor pains with a pain of standard intensity which was produced by a three-second exposure to thermal radiation on the dorsal surface of the right hand. The pain evoked on the hand had been previously standardized into $10\frac{1}{2}$ units of painfulness ($10\frac{1}{2}$ dols) between the threshold pain and the most intense pain which can be experienced (ceiling pain).

2. The pain intensity was observed to change with the progress of labor as follows:

- a. First stage—

First quarter—threshold to two dols

Second quarter—three to five dols

Third quarter—five to seven dols

Fourth quarter—seven to ten dols.

- b. Second stage—Ceiling pain, ten to ten and one-half dols.

- c. Fourth stage—Intensity from three to five dols to near threshold value in about two hours after delivery.

3. The intensity of the pain in the first stage of labor was roughly proportional to the extent of cervical dilatation and inversely proportional to the duration of the interval between uterine contractions. Pain intensity can be estimated approximately by the formula:

$$\text{Dols} = 10.5 - 1.5 \times \text{contraction interval in minutes.}$$

4. The duration of pain was 15 per cent of the contraction time for the weak contractions characteristic of early labor, and 95 per cent of the contraction time at the beginning of the second stage of labor.

5. The pain threshold was measured in the interval between contractions in the first, second and fourth stages of labor. It was within the normal range for all the patients who had received no analgesia or anesthesia.

6. The intensity of the pain experienced by the patient could not always be evaluated on the basis of her reaction, nor correlated with her apparent distress. Distinguishing between the intensity of the pain perceived by the patient and the patient's reaction has been made possible by measurements of pain intensity and pain thresholds.

METHODS FOR MEASURING THE ACTIVITY OF COMPONENTS OF THE STREPTOCOCCAL FIBRINOLYTIC SYSTEM, AND STREPTOCOCCAL DESOXYRIBONUCLEASE¹

By L. R. CHRISTENSEN

(From the Department of Microbiology, New York University College of Medicine, New York City)

(Received for publication September 22, 1948)

Studies of the effects of streptokinase and desoxyribonuclease from hemolytic streptococci on certain pathological processes, reported in an accompanying paper (1), necessitated the development of quantitative methods suitable for routine laboratory assay of the various substances known to affect the streptokinase-plasminogen (streptococcal fibrin-lysing) system. Methods were devised, or earlier methods modified, for the routine assay of streptokinase (streptococcal fibrinolysin), antistreptokinase (antifibrinolysin), serum inhibitor (serum trypsin inhibitor), and plasminogen (serum protease, serum fibrinolysin, serum trypsin).

MATERIALS

1. *Crude streptokinase*:² The method used for production of streptokinase is based on one previously published (2), but differs principally in the use of ethanol as a precipitant rather than ammonium sulfate.

Cultures of Group C strain H46A are grown in the presence of high glucose concentration, employing intermittent neutralization with NaOH in the manner previously reported (2). The yields of streptokinase and desoxyribonuclease from a typical culture are presented in Figure 1. It will be noted that the peaks of enzyme production coincide with the peak of glucose utilization. As incubation is continued, both streptokinase and desoxyribonuclease levels decline. For this reason it is best to begin harvesting of the culture shortly before glucose utilization ceases.

At the end of the growth period the cells are removed by Sharples centrifugation at about 40,000 rpm. The supernatant is adjusted to pH 3.8-4.2 by the addition of glacial acetic or hydrochloric acid. Cold ethanol at -8°C is added to the supernatant at room temperature to a final concentration of 40-50%. After standing overnight in the cold, the practically clear supernatant is siphoned off and the flocculent precipitate, which contains the streptokinase and desoxyribonuclease, is collected by centrifugation at 2,000-3,000 rpm. The precipitate is dissolved in borate buffer with the aid of alkali, adjusted to pH 7.8-8.0, and lyophilized. This precipitate contains the cells not sedimented by Sharples centrifugation, vari-

¹ Desoxyribonuclease.

ous streptococcal proteins, some media components, nucleic acids, streptokinase and desoxyribonuclease.

2. *Purified streptokinase*: The purification procedure is a modification of an earlier method (3). A 2-5% solution of crude streptokinase is made

¹ This study was supported in part by a grant from the Life Insurance Medical Research Fund and the Ralph B. Rogers Rheumatic Fever Fund.

² We are greatly indebted to Dr. Benjamin Carey and Mr. J. N. Adam, Jr. of the Lederle Laboratories Division of the American Cyanamid Company for supplying large quantities of crude streptokinase for these studies.

in borate buffer, pH 7.8–8.0. Cells and insoluble debris are spun out at 16,000 rpm in a refrigerated angle centrifuge. Occasionally a significant portion of the activity is also spun down by this treatment. If this is the case, the precipitate is resuspended and made alkaline to thymol blue (above pH 9). The solution is then adjusted to pH 7.8–8.0 and centrifuged. Following this treatment the activity remains in solution. The supernatants are pooled and diluted with distilled water to a nitrogen content of about 0.25–0.50 mg./ml. and sufficient Pillimer's acetate buffer is added (4) to reduce the pH to 5.6. Sufficient 1% protamine³ solution in distilled water is added to cause the formation of a flocculent precipitate (usually about 1 ml./5–10 mg. nitrogen). The protamine precipitate is spun out in a refrigerated angle centrifuge at 4,000–5,000 rpm. The supernatant should show no further precipitation on testing with protamine, but care should be used to avoid any great excess of protamine, since it will complicate later purification steps. The supernatant is cooled to about 0° and ethanol at –10° to –20° is added to a final concentration of 20%. On standing overnight at –8° to –10° a flocculent precipitate forms which is spun off in an angle centrifuge in the cold. The precipitate is dissolved in borate buffer, pH 7.8–8.0. Some insoluble material remains in suspension, but in most cases little activity is associated with it; and it can be removed by centrifugation, resulting in little or no decrease in total activity, but a decrease of about 50% in total nitrogen. The clear solution usually contains between 100 and 180 units of streptokinase per microgram of nitrogen. Recovery usually represents about 25% of the original activity of the culture, some 50% of the original activity being lost during the initial Sharples centrifugation. Desoxyribonuclease, which has accompanied streptokinase in the previous purification steps, is separated from streptokinase by the 20% ethanol fractionation.

³ Several sources of protamine have been tested. In our experience, consistently good results are obtained with Squibb protamine. Protamines from other sources often fail to effect purification, and are less efficient in that much larger quantities are necessary to precipitate inert materials. We wish to express our gratitude to E. R. Squibb and Sons for generous gifts of protamine.

Practically all of the desoxyribonuclease activity remains in the supernatant.

The purified streptokinase is sterilized by filtration through Seitz or Sela filters, lyophilized and stored in the refrigerator. Solutions remain stable for several weeks if not too dilute and if kept in the cold.

3. *Streptococcal desoxyribonuclease*: As mentioned in previous reports (5–7), streptococcal cultures contain a potent desoxyribonuclease. In the original method of purification (2) using ammonium sulfate, both enzymes were found in the same fraction. However, they are readily separated since streptokinase is precipitated at pH 5.6 by 20% ethanol or 50% ammonium sulfate, while the majority of the desoxyribonuclease remains in solution. In the present study, desoxyribonuclease was prepared by bringing the 20% ethanol supernatant of the above protamine-purified streptokinase precipitate to 40–50% ethanol. The precipitate which forms overnight in the cold is collected by centrifugation and dissolved in the gelatin-magnesium-veronal buffer recommended for desoxyribonuclease titration by McCarty (8). The preparations usually contain insoluble material, with which is associated some of the desoxyribonuclease activity. The clear supernatant obtained by centrifugation of the material, however, contains a significant proportion of activity.

Up to the present time methods have not been perfected for the quantitative isolation of the enzyme from streptococcal cultures and recovery represents only a fraction of the amount in the

TABLE I
Fractionation of streptokinase and desoxyribonuclease from streptococcal cultures

Fraction	Total units	
	Streptokinase	Desoxyribonuclease
(1) original culture	1.75×10^6 units	5.25×10^4 units
(2) after Sharples centrifugation	1.5×10^6	4.1×10^4
(3) alcohol precipitate of culture supernatant	$1.2 \times 10^{6*}$	3.0×10^4
(4) 20% alcohol ppt. of protamine supernatant	1.38×10^6	0.1×10^4
(5) 40% alcohol ppt. of (4) supernatant	0.01×10^6	1.8×10^4

* This value is somewhat lower than the true value because sufficient time for reversal of the inactivation, which occurs in the neighborhood of pH 5 (3), was not allowed before titration.

original culture. This loss is due apparently to the instability of the enzyme.

In Table I are presented the data obtained in a typical purification experiment.

4. *Bovine fibrinogen*: For reasons to be discussed later, human fibrinogen preparations were considered unsuitable for assay purposes. Armour's Fraction I of bovine plasma,⁴ a commercial product, has been found to be quite suitable for our purposes, since it contains no antistreptokinase, serum inhibitor or plasminogen activatable by streptokinase. The dry powder is stored in the refrigerator and dissolved in borate buffer, pH 7.4-7.6, in appropriate concentrations before use. Solutions are reasonably stable and generally remain usable for six to eight hours if kept cool.

5. *Plasminogen*: No satisfactory preparation of plasminogen is available. The purer preparations with which we are familiar, such as Howard Fraction III-2,3 (9), contain plasmin as well as plasminogen and proteolytic products of fibrin. The cruder preparations, prepared by salt fractionation (2), isoelectric precipitation (2, 10) or ethanol fractionation, such as Harvard Fraction III (11), contain a variety of substances, some of which undoubtedly influence the streptokinase-plasminogen reaction. However, reproducible results have been obtained in these laboratories by using a single lot of Harvard Fraction III.⁵ For use, the material is made up in borate buffer in a concentration of 0.25%. The solutions must be used immediately, and kept in an ice bath, because some spontaneous plasmin activity will develop in a few hours. However, when used as outlined, we have noted no variation in the plasminogen titer of the dry material in over a year.

6. *Standard antistreptokinase*: A pool of Harvard Fraction II-III was fractionated by Harvard method 9 (12). Fraction II, the antibody fraction, was lyophilized and stored in a vacuum desiccator.⁶ Assay of the material with strepto-

kinase indicated that 1 mg. would inhibit the activity of 10 units of streptokinase, when tested by the method outlined below. The material was assigned, therefore, a value of 10 antistreptokinase units per mg., and used throughout these studies as a primary standard to check the constancy of the streptokinase unit and of the antistreptokinase titrations.

7. *Crystalline trypsin*: A solution of commercial crystalline trypsin, obtained from the Plaut laboratories, is prepared in N/400 HCl. The stock solution contains 0.1% of the dry powder, of which about 50% is magnesium sulfate. The concentration of active trypsin in the solution is determined by titration with soybean inhibitor, as outlined below, and appropriate dilutions for use, usually containing 20 μ g. of active trypsin per milliliter, are made up in borate buffer immediately before use.

8. *Crystalline soybean inhibitor*: A stock solution of Kunitz' crystalline inhibitor⁷ (13), containing 2 mg./ml. of inhibitor, was prepared in borate buffer. Appropriate dilutions are made up in borate buffer, pH 7.4-7.6, before use.

9. The preparation of other reagents, such as borate buffer and gelatin buffer, have been detailed in previous reports (2, 14).

METHODS

1. *Streptokinase assay*: Many methods have been described for streptokinase assay, utilizing clots prepared from human fibrinogen (15-18). These methods depend on the presence of plasminogen as a contaminant of the fibrinogen preparations, since, as Milstone (10) has shown, highly purified human fibrinogen will not lyse in the presence of streptokinase unless another serum factor (lysin factor, plasminogen) is added. In our experience, methods utilizing human fibrinogen are unsuitable for long-term routine use. The principal disadvantage is the variation from batch to batch in the fibrinogen-plasminogen ratio obtained with different methods of prepa-

Physical Chemistry of the University of Wisconsin for making facilities available and for help in the preparation of various plasma fractions.

⁷ Dr. M. Kunitz kindly supplied us with a preparation of crystalline soybean inhibitor for use as a standard, and made available his assay methods in advance of publication.

⁴ We are indebted to Dr. J. B. Lesh of Armour Laboratories for supplying the Fraction I used throughout this study. Fraction I is an ethanol fraction of bovine plasma and consists largely of fibrinogen.

⁵ We are indebted to Dr. Dwight Mulford, Division of Biologic Laboratories, Massachusetts State Department of Health, for supplying a large lot of Fraction III isolated from a single pool of plasma.

⁶ The author wishes to express his indebtedness to Dr. J. W. Williams and associates of the Department of

ration, and even with the same method. For example, in our experience ethanol fractions of plasma, such as Harvard I, contain less plasminogen than do the salt fractionations previously used in this laboratory (2), as shown by the fact that clots treated with streptokinase will lyse much more readily if the fibrinogen is prepared by salt fractionation rather than the ethanol. Also, human fibrinogen preparations are unstable, due to the spontaneous conversion of plasminogen to plasmin. Another difficulty in the use of human fibrinogen is the presence of variable amounts of antibody globulin in the preparations. While on these occasions no particular difficulty with most samples of normal plasma whatever the method of fractionation, we have encountered occasional lots of plasma with such high titers of antistreptokinase that they were unusable.

For these reasons, we have modified the test by the substitution of clots prepared from bovine fibrinogen (Armour's Fraction I). The bovine fibrinogen contains no plasminogen or plasmin, as shown by the fact that such clots, without added protease, will remain stable for days in the presence or absence of streptokinase. Antistreptokinase and inhibitor titrations indicate the absence of these substances also. As a source of plasminogen we have used a single large lot of Harvard Fraction III. The fibrinogen concentration used is 0.1%, as in previous reports, and the concentration of Fraction III is adjusted to give a streptokinase unit equal in value to the one previously employed in this laboratory (3). The streptokinase assay is performed as follows:

- 0.1 ml. streptokinase dilution in gelatin buffer
- 0.4 ml. bovine fibrinogen, 0.25% in borate buffer
- 0.5 ml. Fraction III, 0.25% in borate buffer.
(This solution must be prepared just before use, and should be kept on ice)
- 0.1 ml. Lederle Hemostatic Globulin,⁸ diluted 1:3 in borate buffer.

⁸ Lederle Hemostatic Globulin has recently become unavailable. Parke-Davis bovine thrombin may be substituted as well as Upjohn thrombin. They are less stable than Hemostatic Globulin when in solution in borate buffer, and solutions must be titrated frequently to determine the minimum amount necessary to form a firm clot. These preparations are more stable in glycerol solution, but we have not used glycerol solutions.

The tubes are incubated at 35° and the lysis time of each tube of the series noted. The dilution lysing the clot in 10 minutes contains one unit and is determined by interpolation as outlined in a previous report (3).

2. *Antistreptokinase*: The antistreptokinase unit is defined as the amount of antibody required to inhibit 1 unit of streptokinase to such a degree that it will not activate the plasminogen sufficiently to cause lysis of the standard test clot in 30 minutes. Other methods of antistreptokinase assay have been presented (15, 18-20) but no general agreement has been reached on a method. We have thought it preferable to base the antibody unit on the method of streptokinase titration used in this laboratory. In order to have a primary standard of reference throughout the study, a lot of Fraction II, the gamma globulin fraction of human serum, was prepared and lyophilized. This preparation contained 10 antistreptokinase units per mg., and has been used as a reference standard for streptokinase and antistreptokinase titrations. Standardization of streptokinase with standard antibody is performed as follows:

- 0.5 ml. streptokinase dilutions in gelatin buffer, pH 7.6-7.8
- 0.5 ml. standard antibody solution, containing 2 antistreptokinase units per ml. (The antibody solution is heated at 56° for 30-45 minutes to destroy the small amount of plasminogen and inhibitor which it contains.)

The mixture of streptokinase and antibody is incubated at 35° for 30 minutes. At the end of this time, the following reagents are added:

- 0.5 ml. of a 0.25% solution of Fraction III
- 0.5 ml. of 0.5% bovine fibrinogen
- 0.1 ml. Hemostatic Globulin, diluted 1:3.

The tubes are incubated for another 30 minutes and the highest dilution of streptokinase which fails to lyse the clot is taken as the end point. A solution of crude or purified streptokinase standardized in this manner should show no significant change in titer over a period of a week or two if the streptokinase concentration is above about 2,000 units per ml. for the crude and above

10,000 units per ml. for the purified. More dilute solutions are not quite so stable, probably because of denaturation occurring in dilute protein solutions. However, in practice, the streptokinase solution is standardized every day or two.

In determining the antistreptokinase titer of serum the serum must be heated at 56° for 30–45 minutes to destroy the plasminogen and inhibitor which it contains. As may be seen in Table II,

TABLE II
Effect of heating serum at 56° C for 30 minutes on serum inhibitor and antistreptokinase

Serum number	Inhibitor equivalent to micrograms trypsin		Antistreptokinase	
	before heating	after heating	before heating	after heating
1	1000	100	128	128
2	500	80	64	64
3	1000	—80*	64	32
4	667	100	64	32
5	667	—80*	128	64
6	667	—80*	16	8
7	1800	120	2560	2560
8	800	48	3200	3200

* Inhibitor equivalent to less than 80 μ g.

heating reduces the inhibitor concentration by approximately 90%, and produces no significant change in the antibody titer. A more valid reason for heating the serum than for the inactivation of inhibitor is to destroy plasminogen, since if this is not done, in the case of sera with a low antibody content, the tubes containing the lowest dilutions of serum will lyse the standard clot because of the activation of the plasminogen in the serum by uncombined streptokinase.

The inactivated serum is titrated for antistreptokinase as follows:

0.5 ml. inactivated serum dilution

0.5 ml. streptokinase solution, diluted in gelatin buffer to contain about 1–2 units.

The tubes are incubated for 30 minutes, and the remainder of the titration carried out as above. The end point is taken as the highest dilution of serum preventing lysis of the clot, and contains antistreptokinase equivalent to the streptokinase in the test.

3. *Serum inhibitor*: A number of methods have been devised in the last few years for the quantitative estimation of serum inhibitor (14, 18, 21–

23). These methods, however, have certain disadvantages for routine use.

Kunitz (13) has shown that crystalline soybean inhibitor undergoes an immediate, stoichiometric, irreversible reaction with trypsin, and that active trypsin can readily be determined by titration of the amount of soybean inhibitor necessary to inhibit the proteolytic activity of the trypsin sample, since the two are equivalent, weight for weight. Schmitz (24) has isolated a small amount of inhibitor from serum which he concluded was probably identical with the pancreatic inhibitor. It has also been shown (14) that serum and pancreatic inhibitor behave in the same way toward trypsin and toward plasmin, although the two inhibitors behave toward trypsin in a quantitatively and perhaps qualitatively different manner than they behave toward plasmin. In view of these facts it was decided to determine the inhibitory power of serum in terms of its ability to inhibit trypsin rather than plasmin. Additional reasons influencing this decision were as follows: (a) crystalline trypsin is readily available and easily standardized, whereas no plasmin preparations of comparable purity are known; (b) trypsin is much more susceptible to the action of inhibitor than is plasmin; and (c) active trypsin can be conveniently stored in a stable solution (in M/400 HCl) while plasminogen and plasmin preparations are very unstable (14, 25, 26).

Standardization of trypsin with soybean inhibitor is carried out as follows:

0.5 ml. freshly prepared dilutions of stock trypsin in borate buffer, pH 7.4–7.6

0.5 ml. soybean inhibitor, usually containing 10 μ g.

1.0 ml. bovine fibrinogen, 0.2% in borate buffer.

The tubes are incubated for 10 minutes at 35°. At the end of this time 0.1 ml. of Hemostatic Globulin, diluted 1:3, is added and the formation of clots noted in 5–10 minutes. The method is based on Ferguson's (27) procedure for the fibrinogenolytic assay of tryptases. The lowest dilution of trypsin in which a clot forms contains trypsin equivalent to the soybean inhibitor in the test. It is necessary to allow the trypsin to act in the absence of Hemostatic Globulin because the Hemostatic Globulin preparations used con-

tain some trypsin inhibitor.⁹ An advantage to this procedure, however, is that the addition of Hemostatic Globulin stops all tryptic activity, so that once the clots are formed, they are stable. Any desired range of trypsin concentration can be titrated by this method by using appropriate concentrations of inhibitor in the test. The sensitivity obtained depends on the interval between successive trypsin dilutions.

The inhibitor concentration of serum is determined as above with the substitution of dilutions of serum for the soybean inhibitor and the substitution of a fixed amount of active trypsin, usually about 10 μ g., for the trypsin dilutions. The tube containing the highest dilution of serum in which a clot forms on addition of thrombin contains serum inhibitor equivalent to the trypsin in the test. Results are expressed as micrograms of active trypsin inhibited by 1 ml. serum.

The accuracy of the fibrinogenolytic test was compared with the method of Kunitz (13) for determining trypsin inhibitor, with results as shown in Table III.

TABLE III

Comparison of methods for serum inhibitor determination
Inhibitor equivalent to micrograms trypsin
inhibited per ml. serum

Serum number	Kunitz method	Fibrinogenolytic method
1	520	500
2	490	500
3	590	660

4. *Plasminogen*: Plasminogen determinations of serum are of doubtful accuracy because plasminogen cannot be separated quantitatively from serum, nor can the interfering substances, antistreptokinase and serum inhibitor, be removed or destroyed without loss of plasminogen. However, in samples of sera which are not abnormally high in antibody or inhibitor, the relative concentrations of plasminogen can be determined by activating with streptokinase and determining the least amount of activated serum necessary to lyse a standard clot. The details of the determination are as follows:

0.5 ml. serial dilutions of serum in borate buffer

⁹ As noted above, Hemostatic Globulin is no longer available. Preliminary experiments with the more highly-purified bovine preparation of Parke-Davis indicates that they contain little or no inhibitor.

0.1 ml. streptokinase solution, previously standardized as outlined below

0.4 ml. bovine fibrinogen, 0.5% in borate buffer

0.1 ml. Hemostatic Globulin, diluted 1:3.

The highest dilution of serum lysing the clot in 30 minutes at 35° represents one unit of plasmin, or plasminogen.

It is necessary to activate the plasminogen in the presence of substrate, because, if this is not done, the total protease activity declines rapidly, probably because of the two-fold effect of auto-digestion (25) and combination with serum inhibitor. Activation in the presence of substrate appears to minimize these effects. Since the activation of plasminogen by streptokinase appears to be a catalytic reaction (2, 14, 28-31) it will be most efficient when an excess of streptokinase is used. A large excess of streptokinase would also prevent interference with the reaction by the antistreptokinase contained in variable amounts in practically all human sera. When attempts are made to use maximal amounts of crude streptokinase to activate serum plasminogen, an inhibitory effect is noted. This inhibitory effect of undiluted, concentrated crude streptokinase is due, probably, to the presence in crude streptokinase preparations of a protease inhibitor (14) which decreases in amount as streptokinase is purified. When purified streptokinase is used to activate a serum, maximum protease activity is obtained with the highest concentration of streptokinase, as shown in Table IV.

TABLE IV

Plasminogen activity of serum activated with various concentrations of purified streptokinase

Purified streptokinase dilution	Highest dilution of serum causing lysis in 30 minutes
undiluted	5120
1:10	5120
1:100	1280
1:1000	160

In addition to the absence of an inhibitory effect of high streptokinase concentration when using purified material, it can be seen from the data in Table V that the activity obtained is considerably higher than with the crude material. It is obvious, therefore, that activation with purified material is the method of choice. Unfortunately, it has not been possible in the past to obtain sufficient purified material for all requirements of the stud-

ies involved in these reports. Therefore, protease determinations were made with selected batches of crude streptokinase, titrated to determine those lots and dilutions which would give the highest

are presented the results obtained by using the methods described above.

TABLE V

Relation between maximum plasmin activity developed in serum by crude and purified streptokinase

Serum	Maximum plasmin activity	
	Crude streptokinase	Purified streptokinase
L (6-19-48)	1280	3200
L (7-16-48)	640	1600
S	320	1280
B	160	1280
F	320	2560

values with normal sera. Such lots were set aside and used in all the protease determinations reported in the present studies. The results obtained, while not representing the maximal values, are useful as a measure of the relative plasminogen content of sera. The validity of this assumption is borne out by the observation (Table V) that a direct relation exists between the maximum amount of protease activity obtained on the activation of serum with crude and with purified streptokinase.

5. *Desoxyribonuclease*: The determination is carried out as described by McCarty (7), except that drop in relative viscosity is measured over a 10-minute instead of a 20-minute period of incubation. A unit is defined as the amount of enzyme necessary to cause a drop of 1 viscosity unit in 10 minutes at 30° in a reaction mixture consisting of 2.4 ml. of desoxyribose nucleic acid and 0.1 ml. enzyme solution. The substrate consisted of a 0.15-0.2% solution of thymus desoxyribose nucleic acid in veronal buffer. The nucleic acid was prepared as described by Mirsky (32). Difficulty was encountered with the nucleic acid solutions in that a spontaneous drop in viscosity was noted. This effect could be eliminated by heating the nucleic acid solution to 56° for about an hour. The heated solution, when used in the reaction mixture described above, had an initial relative viscosity of 4-5 units.

RESULTS

1. *Antistreptokinase*: Evidence is abundant that an antibody to streptokinase appears following streptococcal infection (18, 33-36). In Table VI

TABLE VI
Antistreptokinase levels in various sera

Serum	No. samples	Antistreptokinase units	
		Mean	Range
Normal	14	36	4-80
Infants (under 1 year)	9	8	0-29
Rheumatic fever (children)	8	1302	100-4200
Streptococcal pharyngitis	3	92	80-115
Tuberculous pleurisy	22	87	2-400
Dog	3	102	72-156
Monkey	1	66	
Cow (pool)		8	
Horse (pool)		4	
Chicken	1	32	

Direct evidence that antistreptokinase is produced in humans following injection of streptokinase has been obtained in the present series of studies and is reported more fully in the accompanying paper (1). In Table VII are shown the antibody titrations in the serum of two patients following the intrapleural injection of purified streptokinase. The antibody responses seen in the two patients reported in Table VII are perhaps

TABLE VII

Rise in antistreptokinase following intrapleural injection of purified streptokinase

Patient	Date	ASK units
M. H. (female)	6/8 (200,000 SK injected intrapleurally)	20
	6/11	80
	6/17	5120
	6/22	over 10,000
C. L. (male)	5/13 (50,000 units Sk injected intrapleurally)	40
	5/17 (100,000 units SK)	—
	5/20	5120
	6/9	over 10,000
	6/22	over 10,000
	7/2	5120

somewhat more rapid than is usual as a primary response to the injection of an antigen. The rapidity of the response, however, is probably due to the fact that the response is an anamnestic one, since it will be noted that both patients had a titer before injection of streptokinase. In fact, all human sera tested have had some antibody, even

with no known history of streptococcal infection.

2. *Serum inhibitor*: The values obtained for a variety of sera are presented in Table VIII. Results are expressed as micrograms of active trypsin inhibited by 1 ml. of serum.

TABLE VIII

Serum inhibitor levels of serum from man and animals

Serum	No. of samples	Serum inhibitor as micrograms trypsin inhibited per ml.	
		Mean	Range
Normal adult	16	655	100-1200
Infants (under 1)	9	613	420-1024
Rheumatic children	5	760	570-900
Pulmonary tuberculosis	7	1035	660-1500
Carcinoma	4	883	600-1333
Leukemia	5	1096	842-1350
Chicken	1	264	
Rabbit	1	400	
Horse (pool)	2	765	670-860
Dog	1	365	
Guinea pig	2	2125	1750-2500

The data presented are obviously too scanty to warrant the drawing of conclusions. However, the finding that the value is elevated in chronic wasting diseases such as tuberculosis and malignancies is in accord with many earlier observations on serum inhibitor (see Grob [21] for references).

The values for animal sera tested lie within the range of normal human values, with the exception of guinea pigs, which, at least in the few specimens tested, have an abnormally high value.

TABLE IX

Levels of plasminogen in various sera

Serum	No. of specimens	Units of plasminogen	
		Mean	Range
Normal adult	8	572	160-1280
Rheumatic children	3	960	320-1280
Tuberculosis	6	4053	1280-5120
Carcinoma	1	2560	
Non-rheum. H. D.	5	576	320-640
Chicken	1	Less than 10 units	
Monkey	2	Less than 10 units	
Dog	3	Less than 10 units	
Cattle (pool)	1	Less than 10 units	

Of interest are the somewhat higher values for rheumatic children. If these differences are significant, their relation to the higher plasminogen values obtained for rheumatics (Table IX) is of

importance, suggesting the possibility that the inhibitor might serve a role in relation to plasminogen. However, when one considers the inhibitor and plasminogen values obtained with animal sera, no relationship appears to exist, since the inhibitor level is high while the amount of plasminogen activatable by streptokinase is negligible.

3. *Plasminogen*: The deficiencies of the method for plasminogen determination have been discussed above. The results obtained are presented in Table IX.

In spite of the deficiencies of the method, the results obtained with normal sera have been reasonably uniform, the great majority of them showing levels of 320 or 640 units. Retitration of a single serum, or titrations of successive bleedings of the same individual show a variation of no more than one tube in the series. The higher values obtained with certain of the patients under investigation (*e.g.*, tuberculous and carcinomatous) probably represent an increase over normal, even though the method of titration does not give maximal values for any serum. If these values are artifacts and do not represent an increase of total plasminogen over normal, it is difficult to account for the results, since the two substances in serum known to influence the reaction, serum inhibitor and antistreptokinase, would both tend to decrease, rather than increase the plasminogen values.

SUMMARY

A method for purification of streptokinase describes conditions for obtaining high yields from bacterial cultures. Protamine is used to remove impurities and streptokinase is separated from desoxyribonuclease with cold ethanol at 20% concentration. The desoxyribonuclease is precipitated with 40-50% cold ethanol. The yield of streptokinase is about 25% and the product so obtained has been used in clinical studies.

Methods are briefly described for the quantitative estimation of streptokinase, antistreptokinase, serum inhibitor, serum plasminogen, and desoxyribonuclease. These methods were employed to make a survey study of various sera. There is a marked rise in antistreptokinase activity following intrapleural injection of streptokinase in human beings. Serum from the normal

adult contains more antistreptokinase than serum from the infant and the level is strikingly high in rheumatic fever. In various species the concentration decreases in the following order: dog, monkey, man, chicken, cow and horse. Serum inhibitor levels show elevations in wasting diseases, and in the animals studied the guinea pig has an exceptionally high inhibitor titer. The method for plasminogen determination presents difficulties but it appears that there may be a marked increase in patients with tuberculosis. The concentration in chicken, monkey, dog, and cattle appears to be low.

Serum can be heated at 56° C for 30 minutes to destroy serum inhibitor but antistreptokinase is not destroyed.

THE EFFECT IN PATIENTS OF STREPTOCOCCAL FIBRINOLYSIN (STREPTOKINASE) AND STREPTOCOCCAL DESOXYRIBONUCLEASE ON FIBRINOUS, PURULENT, AND SANGUINOUS PLEURAL EXUDATIONS¹

By WILLIAM S. TILLET AND SOL SHERRY

(From the Department of Medicine, New York University College of Medicine, and the Third Medical Division of Bellevue Hospital, New York City)

(Received for publication August 6, 1948)

The results described in this article were obtained by the injection of concentrated and partially purified preparations derived from broth cultures of hemolytic streptococci into the pleural cavity of selected patients who were suffering from different types of diseases that gave rise to pleural exudations. The possibility has been explored of utilizing two of the defined properties elaborated by hemolytic streptococci that have the unique capacity of causing rapid lysis of the solid elements (fibrin and nucleoprotein) that are significant parts of exudates. In a companion article, Christensen (1) has described additional steps in the purification of the materials employed and has given quantitative methods of measurement of various increments concerned in the fibrinolytic system, including trypsin inhibitor and specific antibodies, which have been employed in this study.

In the study of patients it was first necessary to: (a) develop the investigation within non-toxic but effective ranges of doses of the material employed, and (b) determine whether or not the enzymatic activities of the streptococcal products were effectively operative when introduced directly into the site of the disease in the patients. This article is essentially limited to findings that are pertinent to the two aspects of the study mentioned above.

A brief description of the two streptococcal products that have been the subject of the investigation is as follows:

I. *Streptococcal fibrinolysin* (2) (*Strepokinase*)

This has been found to be elaborated characteristically by strains of hemolytic streptococci (Group A) causing acute infections in patients. It is also produced by some strains of strepto-

coccal groups C and G (3). The product is abundantly excreted into the culture medium in which the organisms are grown and is readily obtainable free from the bacterial cells in sterile filtrates.

The fibrinolytic action, in tests conducted under optimal laboratory conditions, is unusually rapid in action on the fibrin coagulum of normal human blood, requiring only a few minutes when whole plasma is employed as a source of fibrin, and an even shorter time when preparations of fibrinogen and thrombin of human origin are used. The ultimate proteolytic nature of the fibrinolysis has been evident in the liberation of breakdown products of protein digestion (4).

Another interesting feature of the phenomenon is the high degree of activity of the streptococcal lytic system in the presence of normal human blood as contrasted with its inaction or delayed effect when tests are conducted with the blood of various animal species with the exception of monkeys (3). Although studies of factors involved in streptococcal fibrinolysis have indicated a basis for the differences in the behavior of blood from different animals, nevertheless the existence of the difference has rendered impossible most experimental studies, *in vivo*, on animals and has limited them to observations conducted in patients, such as those initially described in this article.

The mechanism of the reaction has been a subject of study by various investigators.

In an earlier report (2) it was noted that fibrin formed from mixtures of either human fibrinogen and rabbit thrombin, or of rabbit fibrinogen and human thrombin were susceptible to streptococcal lysis, whereas the fibrin derived from rabbit fibrinogen plus rabbit thrombin was unaffected. Milstone (5) demonstrated that an increment of human serum present in the euglobulin fraction,

¹ This study was supported by a grant from the National Institute of Health, United States Public Health Service.

was necessary for the reaction to occur and that if preparations of human fibrinogen and thrombin were highly purified no lysis would occur when the streptococcal product was added. Furthermore, if this human globulin fraction was added to fibrin made up of rabbit components, lysis occurred. He referred to the euglobulin constituent of human blood as "lysing factor" and suggested that streptococcal fibrinolysis was mediated by the same system as that involved in other examples of fibrinolysis.

Christensen (4), and Christensen and MacLeod (6) have presented results concerning the mechanism, and have concluded that the streptococcal product to which they have given the name streptokinase acts as a catalyst or kinase in causing the transformation of a zymogen of normal human blood, designated by them plasminogen, into a proteolytic enzyme, designated plasmin.

Kaplan (7) has made extensive studies on several aspects of the mechanism of the streptococcal fibrinolysin-serum protease system. These studies have in part dealt with the dissimilarity of serum protease and trypsin and also with the inhibition of streptococcal fibrinolysis by antiprotease. The findings are predicated upon the kinase nature of the action of the streptococcal product and the identity of the protease of serum as the lysing principle. Ratnoff (8), studying a proteolytic enzyme in human plasma, gave special attention to the fibrinolytic system activated by the streptococcal product and obtained data indicating that the activation of plasma proteolytic enzyme by streptococcal fibrinolysin behaved as if it involved a stoichiometric reaction. This finding implies that the streptococcal product may take an active part in the lytic system rather than exert only a catalytic effect.

Without developing the discussion of the mechanism, it is sufficient to state that the objective demonstration of changes in constituents of pleural exudates that have been effected by the streptococcal fibrin-dissolving system, acting within the pleural cavity of patients, constitutes definitive results around which this report centers. The conditions, unavoidably inherent in the several factors that may be simultaneously operative in association with the processes of disease within patients, makes it impossible at the present time to analyze and identify the mecha-

nism of fibrinolysis that may be responsible for the end results that we have observed.

Nomenclature. The fibrinolytic principle derived from hemolytic streptococci is referred to in this article as *streptokinase*. The kinase type of action of the streptococcal product has been consistently observed by several investigators. However, whether or not its complete activity is solely that of kinase remains to be determined.

The term *fibrin-lysing system* has been employed as an objectively descriptive expression which avoids the different recommendations of various investigators (6, 9-11). The *activatable fibrin-lysing system* may be closely identified with the plasminogen of Christensen and MacLeod (6), and the *active fibrin-lysing system* with their term plasmin.

II. *Streptococcal desoxyribonuclease*

In recent articles the occurrence of desoxyribonucleoprotein in significant amounts in purulent empyematous fluids was reported (12) and its depolymerization by a desoxyribosenuclease found to be present in the concentrated streptococcal filtrates was also described (13).

The solid sediments of the samples of pus were found to contain as much as 30% to 70% nucleoprotein. Since the physical characteristics of desoxyribose nucleoprotein are fibrous and gelatinous, the similarity of its appearance to that of fibrin became a matter of importance in identifying the dual enzymatic systems with which we were dealing; namely, fibrin substrate in the fibrinolytic system, and nucleoprotein substrate acted upon by nuclease. In each instance rapid liquefaction of the respective solid substrate occurred.

Each of the substrates mentioned has been identified in varying amounts in different types of pleural exudation. For example, empyematous pus of bacterial origin is high in its content of nucleoprotein, which is presumably derived from the leucocytes, while the constituent most conspicuously present in hemothorax is fibrin. Fibrinous pleural exudates such as may be encountered in association with pneumonia, pulmonary neoplasm, and other diseases, or the effusions of tuberculous pleurisy have been studied chiefly for the fibrinolytic effect, although from

observations on preparations of the exudates stained by the Feulgen method (12), it is evident that varying amounts of nucleoprotein are present.

*Streptococcal concentrates*²

The preparations employed in this study have been prepared by Christensen according to the method of partially purifying the concentrated filtrates of hemolytic streptococci previously described and further elaborated in the accompanying article (1, 14). A strain of hemolytic streptococcus (H46A) belonging to Lancefield Group C has been employed. This strain is potent in its production of both streptokinase and desoxyribose nuclease (13) and most of the lots of concentrated filtrate used in this study have possessed both properties. In addition it seemed reasonable to assume that since the strain (a group C) was not of patient origin its products might presumably be least likely to contain other noxious, but as yet unidentified, increments associated with acute infections in man and would, therefore, be more desirable for preparing material to be used in patients than would a Group A fibrinolytic strain. All the partially purified and concentrated preparations, with one exception, that were introduced into patients, contained both streptokinase and nuclease. In an additional preparation used in a single patient with hemothorax, the content of nuclease was reduced substantially by Christensen (1) but the streptokinase activity remained unimpaired.

The dosage of streptokinase has been based upon a unit, developed and described in the accompanying article by Christensen (1). The dosages per patient are given in the individual protocols. In general they ranged from 20,000 to 400,000 units. The concentration per cubic centimeter ranged from 2,000 to 40,000 units. The total dose was usually contained in 10 cc. of normal saline solution.

The desoxyribonuclease content of the various preparations of streptococcal concentrates has not yet been elaborated so extensively as that of streptokinase. Christensen (1) has suggested a unit basis which is at present being employed. In general the concentrates contained a ratio of approximately 6,000 units of nuclease to 15,000 units of streptokinase. The nuclease was of special significance in the cases of empyema, and the dosage is given in the description of the results obtained in that group.

Toxicity of streptococcal concentrates. Among the initial studies (2) concerned with the characterization of the streptococcal fibrinolytic phenomenon, preliminary observations (unpublished) were made with respect to the skin reactivity of active filtrates derived from strains of fibrinolytic streptococci. Following intracutaneous injections, areas of local erythema developed that simulated the type of a positive reaction elicited by the erythrogenic scarlatinal toxin. However, by comparative tests in

which both scarlatinal toxin and fibrinolytic filtrates were injected into Dick positive and Dick negative individuals, no correlation was detected. From the limited observations, it seemed reasonable to assume that the primary toxicity of the fibrinolytic filtrate was due either to the fibrinolytic principle itself or to some contaminating product other than the established erythrogenic toxin of hemolytic streptococcal origin.

When the recent concentrates prepared by Christensen (1) in the process of purifying the streptococcal fibrinolytic were being considered for introduction into patients, intradermal tests were performed. Although the concentration of streptokinase was increased many hundred-fold over the preparations of earlier use, the degree and frequency of erythematous reactions were found not to be any greater than those previously encountered nor to be related to the concentration.

Samples of the concentrates were then injected intramuscularly. No reactions occurred that were detectable by the development of local redness, tenderness or swelling, or as a generalized pyrogenic effect. When increasingly large concentrations failed to produce untoward effects intramuscularly, small amounts were introduced intrapleurally into patients with empyema, inflammatory pleural effusions, or hydrothorax.

Without describing the details of the progressive observations following intrapleural injections it may be stated that as the procedures of purification and concentration conducted by Christensen developed, the evidences of toxicity have diminished in relationship to amount injected. The studies have, therefore, up to the present time indicated that the primary toxicity of the fibrinolytic principle or the accompanying desoxyribonuclease is not great and that the transient pyrogenic reaction may be due particularly to contaminating substances still present in even the purest preparations now available.

The manifestations of toxicity when they occurred have consisted of a pyrogenic reaction beginning approximately six to eight hours after the injection, reaching its peak of a rise of one to four degrees at 24 hours after injection and decreasing gradually over the next 24 to 72 hours to the pre-injection level which in some instances was a normal temperature and in others was elevated prior to the injection due to the underlying disease. General malaise accompanied the febrile period. Nausea and gastro-intestinal discomfort were noted in some patients. Local pain, although never severe, was present in some instances, and not in others.

An outpouring of polymorphonuclear leucocytes occurred which was demonstrable 24 hours after the injection and decreased to the pre-injection level within the next two to ten days. The increase in the leucocyte counts ranged from 1,000 to 25,000 cells per cubic centimeter.

The general pyrogenic reaction together with individual symptoms as mentioned, and the local outpouring of cellular constituents did not follow any uniform or correlated pattern, since all of the manifestations were not present to the same degree and some of them were entirely absent. In several instances in which two injec-

² Lederle and Co. have cooperated by growing large volumes of culture and supplying the filtrate in its initial concentrated form.

tions were given, the first may have caused a reaction while the second elicited no toxic response, or the first was silent and the second evoked some reaction. Furthermore, the occurrence of reaction was not clearly related to dosage of concentrate.

In this study a total of 34 injections was given to 23 patients. Utilizing a rise of 1° F in fever as an indication of a reaction—and irrespective of whether or not the patient was febrile before the injection—on 17 (50%) occasions a pyrogenic response was noted.

The degree of reaction appeared to be most directly related to the nature of the patient's disease. In instances where considerable thickening of the pleura was present or other circumstances that may have impaired the absorbing surface, minimum or no toxic reactions occurred. In other cases where the contrary situation of a thin pleura or presumably a relatively freely acting absorbing surface was present, the reactions as described were more consistently noted.

Other factors that may participate in the reaction in a manner as yet undetermined are the breakdown products derived on the one hand from the fibrinogen and fibrin system and, on the other hand, from the nucleoprotein system through the action of nuclease. No specific information on this phase of the subject is available except the fact that the toxic reaction, whatever its exact cause may be, was a transient one of the classical brief pyrogenic type without any residual effects. No indication of chronic alterations of an untoward nature have been evident. Because of the implications of hemolytic streptococci in relation to rheumatic fever and acute hemorrhagic nephritis, detailed examinations for their possible presence have been frequently made with uniformly negative findings.

It has been of special importance to make preliminary tests with each new lot of purified concentrates made available for use in patients by injecting a small amount intrapleurally and noting the degree of reaction. When the reaction appeared to be relatively greater than would be expected from the small dose, the lot was not further employed in the study of patients. This precautionary procedure of selecting individual preparations for intrapleural use has been regularly adhered to, and, as a result, no contraindications for the development of the study have been encountered.

PROCEDURE

Observations on Patients. In the study of patients numerous quantitative determinations have been made on samples of exudate obtained prior to the injection of streptococcal concentrates and at stated intervals thereafter, usually one hour, 24, 48, 72 hours, etc., according to the nature of the case and the findings.

The tests and procedures employed have included the following: fibrinogen, N.P.N., total protein, formal titration, amount of sediment, viscosity, pH, volume of pleural exudate, free streptokinase, activatable fibrin-lysing system, active fibrin-lysing system, trypsin inhibitor, and specific anti-fibrinolytic antibody (anti-streptokinase).

Cytological studies, including total and differential counts, determination of motility and viability of cells and the appearance of Feulgen-stained preparations for the purpose of identifying intra- and extracellular deoxyribose nucleoprotein have also been made. These results will be referred to briefly in this article and be reported in detail in a subsequent communication.

The technical procedures in each instance have been as follows:

Streptokinase titre, activatable fibrin-lysing system (equivalent to plasminogen), trypsin inhibitor, and anti-streptokinase titre were determined on chest fluid according to the methods described by Christensen (1). *Active fibrin-lysing system (equivalent to plasmin)* was determined as follows: To 0.1 cc. samples of chest fluid, brought to neutral pH, were added 0.5 cc. of 0.25% Bovine Fibrinogen (Armour) in 0.01 M saline phosphate buffer (pH 7.4), and 0.5 cc. of 0.25% Human Plasma Fraction III (Cohn) in saline phosphate buffer. One tenth ml. of 1/3 dilution of Lederle Hemostatic Globulin (or 1/500 dilution of Parke Davis Bovine thrombin) in saline phosphate buffer was then rapidly added. The tubes were incubated in a water bath at 37°. One tenth cc. of saline instead of chest fluid was used for controls. The time of complete lysis of the fibrin clot was noted. Since the lysis of fibrin in the absence of extra increments of streptokinase was relatively slow and, therefore, could not be expressed in the same unitage scale, the results were expressed as 0 — + + + + as follows:

lysis up to one hour + + + +
lysis one to six hours + + +
lysis six to 24 hours + +
lysis 24 to 48 hours +
lysis 48 to 72 hours but no lysis in controls ±
No lysis 0

Estimations of the degree of activity of the fibrin-lysing system with respect to time have proved important since the period required for lysis, *in vitro*, reflected to some degree the activity of the process, *in vivo*, which was significant with respect to changes in the exudates that continued for several days after the initial injection.

Amount of sediment: Wintrobe hematocrit tubes were filled to the mark with a heparinized sample of chest fluid and centrifuged at 2,500 rpm for one hour. The results are expressed as per cent.

pH was determined on separately collected heparinized samples by glass electrode after chest fluid was allowed to equilibrate with room temperature. A previously determined temperature correction for the instrument used was applied, so that the results are expressed as pH at 37° C.

Viscosity: The viscosity of thin fluids was determined on heparinized samples in an Ostwald viscosimeter at 37° C. The viscosity of thick purulent fluids was determined with an LV model Brookfield electric viscometer at 37° C.

Total protein and N.P.N. were done on the supernatant of centrifuged oxalated specimens of chest fluid. The total protein was determined by Kjeldahl digestion and nesslerization. The N.P.N. was determined by digestion and nesslerization of a trichloroacetic acid filtrate. The results are expressed as milligrams per cent for N.P.N., and grams per cent for total protein.

Fibrinogen was determined on the supernatant of centrifuged oxalated specimens. Five-cc. samples were diluted to 30 cc. with normal saline, to which were added 1 cc. of 2.5% CaCl₂ solution and 1 cc. of a 1/100 dilution in normal saline of Parke, Davis Bovine Thrombin. The tubes were then placed in the refrigerator overnight. The clots were removed with a stirring rod, washed with distilled water, and the nitrogen determined by digestion and nesslerization. The results are expressed as milligrams per cent.

Formol titration: Ten-cc. samples of heparinized fluid were brought to pH 7.0 by addition of either 0.1 N NaOH or 0.1 N HCl. Five cc. of 40% formaldehyde were added, and the mixture titrated with standard 0.1 N NaOH by glass electrode to pH 8.6. The volume of alkali necessary to bring 5 cc. of 40% formaldehyde to pH 8.6 was subtracted from the titration. The results are expressed as cubic centimeters of 0.1 N NaOH per 100 cc. of chest fluid.

Volume of pleural fluid: Since information concerning the volume of pleural effusions was desirable, the following method was developed. The fluid volume was determined in pleural transudates and non-purulent exudates by injecting known quantities of T-1824 and sampling the pleural fluid from 15 to 60 minutes thereafter. This method is not applicable to purulent empyemas where a significant portion of the dye is bound to the sediment of the fluids and probably to the shaggy pleural surface, but quantitative determinations on non-purulent pleural effusions have yielded satisfactory results.

RESULTS

Twenty-three patients have been studied following the injection of amounts of streptococcal concentrates sufficiently large to bring about definitive and measurable biochemical and biophysical changes in the area of exudation at the site of the injection. Although the general plan of study has been the same in all instances the presentation of the results has been arranged according to a grouping of the cases based on the types of exudates which were present in the pleural cavities of the patients. The changes that have been effected by the concentrates have been found to bear a relationship to the character of the exudates.

The three major groups were: acute fibrinous

pleurisy, bacterial empyema, and hemothorax.³

Group I. Acute fibrinous pleurisy, 13 patients.

Five cases of tuberculous pleurisy with effusion.

Six cases of primary or metastatic malignant pulmonary neoplasm with pleural effusion.

Two cases of congestive heart failure with pleural effusion.

Figure 1 contains data derived from serial determinations of fibrinogen and nonprotein nitrogen made on seven patients before and after the introduction of streptococcal concentrate. The dosages, given in the figure, ranged from 20,000 to 200,000 units of streptokinase, and approximately 20 to 200 units/cc. chest fluid. Three of the patients received a second injection.

The fibrinogen represents the chief parent protein (plus an undetermined amount of solid fibrin) that was acted upon by the fibrin-lysing system, and the N.P.N. represents the end-product of the local proteolysis.

The findings in each of the seven patients demonstrate the rapidity of the beginning decrease in measurable fibrinogen and increase in N.P.N., the samples taken as early as one hour after the injection revealing changes in the values of each. In patient W. H., for example, the immediate drop in fibrinogen was from 41 to 20 mgm.%, and in patient J. G., from 108 to 26 mgm.%. The concomitant rise in N.P.N. in patient W. H. was from 45 to 52 mgm.%, and in patient J. G., from 31 to 41 mgm.%.

In five of the seven patients of the charted group, a further drop in fibrinogen was noted in the specimen obtained 24 hours after the injection, and in each of the seven the N.P.N. either continued to rise or maintained a higher level than that of the pre-injection figures.

Three of the patients received a second injection of streptococcal concentrate; patient C. L. received 100,000 units of streptokinase four days later, patient E. H. received 40,000 units of streptokinase three days later, and patient J. G. received 200,000 units of streptokinase three days later. In each case there was a further abrupt

³ The authors wish to acknowledge the cooperation and many helpful suggestions which they have received from the Attending and Resident Medical and Surgical Staffs of the Chest Service of Bellevue Hospital, Dr. J. Burns Amberson, Director.

FIG. 1. THE EFFECT OF INTRAPLEURALLY INJECTED STREPTOKINASE ON THE FIBRINOGEN AND N.P.N. CONCENTRATIONS OF THE CHEST FLUID OF SEVEN PATIENTS WITH FIBRINOUS PLEURAL EFFUSIONS. The crosses represent N.P.N. (mgm.%), and the circles, fibrinogen (mgm.%).

decrease in fibrinogen and rise in N.P.N. following the second injection.

In five cases in which the fibrinogen content was followed for long periods of time by examining samples of pleural fluid obtained at repeated intervals, the levels of fibrinogen were found to return to the control value only after ten days or one month. Why the fibrinogen remained low for this period of time is not readily apparent.

Continuing lytic action during this period was not evident by the measurements of the active fibrin-lysing system employed. Furthermore, the fibrinogen levels remained low despite the appearance of antistreptokinase, and was independent of the reappearance of additional increments of the activatable fibrin-lysing system through further exudation of serum into the pleural area. It may represent the time necessary for the exudation

additional fibrinogen to occur into the area of pleurisy, or slow proteolysis may have continued but at a rate not determinable by our present methods.

There were in the patients several uncontrollable factors that altered the serial findings as they extended over several days. For example, when the patient's disease was in an acute active state,

there was a continuing increase in the effusion together with the inflammatory constituents. When the disease was stationary or subsiding, the contents of the pleural cavity were not substantially altered during the period of observation. In addition, the variable degree of local irritation caused either by the injection material itself or the breakdown products of proteolysis contributed

FIG. 2. THE EFFECT OF INTRAPLEURALLY INJECTED STREPTOKINASE ON THE FREE STREPTOKINASE, ACTIVATABLE AND ACTIVE FIBRIN-LYSING SYSTEMS OF THE CHEST FLUID OF FIVE PATIENTS WITH FIBRINOUS EXUDATES

In the graphs for each patient, in the top sections the crosses represent the activatable fibrin-lysing system (units/cc.) and the circles the active fibrin-lysing system; in the lower sections, the circles represent free streptokinase (units/cc.).

FIG. 3. THE ANTISTREPTOKINASE TITRE IN PLEURAL EFFUSIONS FOLLOWING INTRAPLEURAL ADMINISTRATION OF STREPTOKINASE IN FIVE PATIENTS WITH FIBRINOUS PLEURAL EXUDATES
Streptokinase was injected at zero time.

an additional increment of exudate. Furthermore, the rate of absorption of the newly formed non-protein nitrogen proceeded at variable rates. Consequently, the figures obtained by analysis of the exudate were only relative with respect to total proteolysis.

In spite, however, of the variables outlined above, the intrapleural degradation of fibrinogen in significant amounts following each injection of the streptococcal concentrates has uniformly occurred in each of the patients in this series, as well as in those of the other groups. The extent to which solid preformed fibrin underwent lysis was not measurable but its breakdown undoubtedly contributed to the N.P.N. that was liberated.

In some of the patients, estimations of blood N.P.N. were done but no significant rise above normal levels was noted, the rate of absorption from the pleural area being insufficient to raise the content of the general circulation.

The data contained in Figure 2 concern three elements involved in the streptococcal fibrin-lysing system, namely: free streptokinase, and both the activatable and the active fibrin-lysing system. They are recorded for five patients of the acute fibrinous pleurisy group. Similar findings were

obtained from most of the patients studied of all the groups.

Prior to injection the amount of activatable fibrin-lysing system present in the pleural exudate was approximately the same as that found in normal serum but within one hour after the injection of streptokinase striking changes occurred in the elements of the fibrin-lysing system of the pleural exudate. When streptokinase was introduced, the activatable elements of the lytic system were replaced by active increments which were demonstrable immediately following injection but progressively disappeared during the next 24 to 48 hours. This implies that once the system assumes the active form it is subsequently destroyed, or disappears through combination with substrate. Its replenishment must await, through further exudation from the general circulation into the local area, the addition of new components of the activatable system which were rapidly depleted following the introduction of streptokinase. The rate at which the replenishment occurred has depended upon factors that control the reformation of exudate. In the series of cases used in this study, it has been demonstrable within a few days. These findings indi-

J.G. - FIBRINOUS EXUDATE

FIG. 4. THE EFFECT OF TWO INTRAPLEURAL INJECTIONS OF STREPTOCOCCAL CONCENTRATE IN A CASE OF TUBERCULOUS FIBRINOUS EXUDATE ON THE FIBRINOGEN, N.P.N., FORMOL TITRATION, TOTAL PROTEIN, FREE STREPTOKINASE, ACTIVE AND ACTIVATABLE FIBRIN-LYSING SYSTEMS, AND THE ANTISTREPTOKINASE TITRE

100,000 units of streptokinase were given in injection 1, and 200,000 units in injection 2.

cate the self-limiting nature of the activity following a single injection of streptokinase.

In our observations trypsin inhibitor has not changed after streptokinase injections and the results indicate that this inhibitor plays little

part under these circumstances in the inactivation of the system.

An excess of free streptokinase was found to be present one hour after the injection but was not demonstrable 24 to 48 hours later. The extent

to which it may be dissipated by combining directly with substrate, or by inactivation by some inhibitor, or by neutralization with specific antibody is not at present determined. Also suggested by the data in Figure 2 is the finding of active fibrin-lysing elements *only* in the presence of free streptokinase. This observation may have a bearing on the mechanism of the phenomenon as it occurs in exudates and will be given further study. However, once the activatable system has been depleted, new increments of free streptokinase alone produce very little new active fibrin-lysing elements.

The development of specific antifibrinolytic antibodies following acute streptococcal infections has been previously demonstrated (15, 16). That the injection intrapleurally of streptococcal concentrates containing streptokinase also evokes the specific antistreptokinase response has been mentioned by Christensen (1), and was observed in connection with the earlier injections which were made primarily to estimate degrees of toxicity.

In Figure 3 evidence is presented from five cases of the development of antistreptokinase antibodies that were demonstrable in pleural exudates and followed intrapleural injections of streptococcal concentrates.

The rise in titre in the exudates occurred between the sixth and 11th days and was noted simultaneously in the serum.

The exact significance of the presence of specific antibody in nullifying the action of the fibrin-lysing system in local areas is not at present clearly established. Subsequent reference will be made to this point in connection with patient A. M. of Figures 7 and 8.

Figure 4 is presented for the purpose of demonstrating the total findings with respect to their correlation obtained serially in a single patient. In addition to the data described in Figure 1 (fibrinogen and N.P.N.) and Figure 2 (activatable fibrin-lysing system, active fibrin-lysing system, and free streptokinase) and Figure 3 (specific antistreptokinase), measurements of total protein and formol titratable substances are included.

The patient, J. G., had acute fibrinous pleurisy of tuberculous origin which had been active for ten weeks when first studied. He received two injections of streptococcal concentrate, the first con-

taining 100,000 units and the second, three days later, containing 200,000 units of streptokinase.

The individual findings are comparable to those presented in Figures 1 to 3 and they demonstrate the rising and falling changes previously described. The fibrinogen drops and the N.P.N. rises; the activatable fibrin-lysing system drops as it is rapidly transformed into the active fibrin-lysing system which attacks the fibrinogen and the local deposit of fibrin; antistreptokinase being evident in increased titre in the exudate on the 11th day.

The *total proteins* have exhibited no quantitative changes. They have been determined in grams rather than milligrams as has been the case with fibrinogen. This is in agreement with Christensen's findings (unpublished) of little or no *in vitro* digestion of serum albumins or globulins.

The formol titrations which have risen coincident with the rise in N.P.N. after each injection were of the same magnitude and probably represent further evidence of the intrapleural breakdown of fibrinogen and fibrin.

The findings in the case of patient J. G. of Figure 4 are similar to those obtained in each of the other cases of Group I. In addition to the results noted in Figures 1 to 4, the following observations have been noted in this group of patients. The pH of the chest fluids fell significantly (0.2 to 0.3 units) in 24 hours after the injection of the streptococcal concentrate, slowly returning to the control values, and has been considered as part of the phenomenon of increased proteolysis. Small but significant falls in viscosity were noted, which are consistent with the breakdown of the long eccentric fibrinogen molecules and depolymerization of any small amounts of desoxyribosenucleic acid that may be present. Twenty-four to 48 hours after injection, the sediment increased from 0.5% to 2.0%, then slowly decreased over the next two to ten days to the control levels. This appeared to be directly related to the increased cellular content occurring in the pleural fluids in association with the local irritation. As noted earlier, no significant changes in the amount of trypsin inhibitor were found in the samples of pleural fluid. Finally, the values for activatable fibrin-lysing system, trypsin inhibitor and antistreptokinase were found to agree

TH. - EMPYEMA

FIG. 5. THE EFFECT OF STREPTOCOCCAL CONCENTRATE (CONTAINING APPROXIMATELY 160,000 UNITS OF DESOXY-RIBONUCLEASE AND 400,000 UNITS OF STREPTOKINASE INJECTED INTRAPLEURALLY), IN A CASE OF MIXED TUBERCULOUS EMPYEMA ON THE ACTIVATABLE AND ACTIVE FIBRIN-LYSING SYSTEMS, FREE STREPTOKINASE, FORMOL TITRATION, N.P.N., VISCOSITY, AND SEDIMENT OF THE CHEST FLUID

The striking change in the character of the fluid is seen in the accompanying photo (Figure 6).

closely for both chest fluid and serum prior to the injection of streptococcal concentrates. The decrease noted in the activatable fibrin-lysing system after streptokinase injections occurred only locally since no changes in this value occurred in the serum at any time. Antibody changes, however, as previously described, were evident simultaneously both locally and in the general circulation.

Group II. Cases of bacterial empyema, Eight patients.

Four cases of mixed infections associated with tuberculous empyema and bronchopleural fistula.

One case of empyema due to Friedlander's bacillus.

One case of pneumococcal (Type XVII) empyema.

One case of post-pneumonic empyema (sterile).

One case of empyema due to anaerobic streptococcus.

Interesting differences were observed between the constituents of purulent empyemal fluid and those of acute fibrinous pleurisy. For example, fibrinogen has not been found to be present in the purulent material aspirated before the injection of the concentrates. The supernatant portion of centrifuged specimens failed to produce coagulum when thrombin was added. It seems probable that the formation of fibrin had previously occurred to a considerable degree at the site of infection and depleted the exudate of its fibrinogen.

In the empyemal group, the presence of desoxyribose nucleoprotein as a significant portion of the granular sediment was regularly noted, and, as previously reported (12), constituted from 30% to 70% of the total solids. In addition, although not recorded in detail in this article, preparations stained by the Feulgen method have revealed the presence of nucleoprotein occurring extracellularly as fibrous reticulum, granules, and amorphous plaques.

In Figure 5 comprehensive data are presented concerning one of the patients with empyema. The patient, T. H., had chronic pulmonary tuberculosis, with a left bronchopleural fistula, draining thoracotomy, and a mixed empyema. After aspirating a sample of pus, streptococcal concentrate containing approximately 160,000

units of desoxyribonuclease and 400,000 units of streptokinase in 10 cc. of saline were injected. The rapid and extensive liquefaction of the nucleoprotein by the desoxyribonuclease was demonstrated by the marked fall in viscosity from 150 \times water to 3 \times water and decrease in measurable sediment from 70% to 23% in one hour. These quantitative changes persisted over the 24 hours of sampling. Subsequent drainage of the empyema was temporarily facilitated following the liquefying changes. However, the lysing procedure was not continued and consequently the clinical value was not extensively tested.

FIG. 6. RAPID LYSIS BY STREPTOCOCCAL CONCENTRATE OF PURULENT PLEURAL EXUDATE WITHIN PLEURAL CAVITY OF PATIENT

Patient T. H. Chr. Pulm. Tbc, lt. bronchopleural fistula, pyopneumothorax and thoracotomy. Streptococcal concentrate containing desoxyribonuclease and streptokinase injected intrapleurally 12/4/47.

Specimen at left: Taken immediately prior to injection. Ten cc. centrifuged for one hour. Sediment 70%—thick, pink, viscid, and containing large cheesy shreds. Viscosity of whole fluid 150 \times water.

Specimen at right: Removed from chest one hour after injection. Ten cc. centrifuged for one hour. Sediment 23%—separates readily into three layers. From bottom up: small viscid layer; large pink layer of mixed red and white blood cells; and white layer composed of white cells and granules. Viscosity of whole fluid 4 \times water.

Definite increases in N.P.N. and formol titratable material were also observed. One hour following the injection the free streptokinase titre was 640 units/cc., and subsequently fell to 10 units/cc. in 24 hours. As in the cases previously described, the active fibrin-lysing system appeared but to a less degree than in the fibrinous pleuritic group.

Even though the above data indicate some degree of activity of the fibrinolytic system, the findings in this patient demonstrate the significant action of the streptococcal desoxyribonuclease. The changes in the physical character of the empyemal pus are strikingly illustrated in the photographs shown in Figure 6. The amount of lysis of sediment that occurred at the site of infection within the patient's thorax is evident and it was to the greatest degree due to the depolymerization of the nucleoprotein of the pus by the nuclease contained in the concentrate that was introduced.

Similar findings were obtained in six of the eight cases of empyema. One of them is worthy of further mention. The patient, T. P., entered the hospital with acute lobar pneumonia of four days' duration. He was treated with penicillin but his course and X-ray were suggestive of empyema. Aspiration of the chest performed on the tenth day of hospitalization yielded only a few cubic centimeters of thick green fluid which was sterile on culture. Introduction of air intrapleurally revealed the presence of several loculations within the empyemal cavity. Ten days later, 50 cc. of thick greenish pleural fluid was withdrawn and streptococcal concentrate containing approximately 40,000 units of desoxyribose nuclease and 100,000 units of streptokinase in 10 cc. of saline was introduced into the site of aspiration. Examination of specimens of fluid obtained by subsequent repeated aspirations revealed that the viscosity of the pus fell from $38 \times$ water to $14 \times$ water in one hour, and to $5 \times$ water in 24 hours. The sediment decreased from 35% to 14% in one hour, and to 10% in 24 hours. The N.P.N. rose from 58 mgm.% to 73 mgm.% in one hour, and to 84 mgm.% in 24 hours. Twenty-four hours after the injection 465 cc. of thin greenish-grey fluid was removed with ease. An X-ray of the chest at this time revealed that the latest aspiration had effected almost complete drainage of

the empyemal cavity and that the previous evidence of loculation had disappeared. Following this tap, the temperature fell rapidly to normal, the leucocytosis disappeared within a few days, and the patient made an excellent clinical recovery.

In one case of mixed empyema and in the one due to Friedlander's bacillus infection, the pHs of the fluids were found to be very acidic (5.50, and 5.21) apparently due to extensive proteolysis and digestion (N.P.N.'s 184, and 400) that had occurred spontaneously as a result of the diseases themselves. The injected streptococcal concentrate had no effect due to the low pH since studies, *in vitro*, have shown that both streptokinase and desoxyribonuclease are rapidly inactivated at this pH.

In cytological studies of the sediment of exudates, both of the acute fibrinous and the purulent groups, one feature of special interest has been the consistent breaking up of clumps of white blood cells. This change has been evident in the contrast between the cells of the pre-injection specimen and those of the sample obtained one hour after the introduction of the streptococcal concentrate. Whether or not the clumping was due to the fact that the cells were made adherent by a coating of fibrin or fibrous-nucleoprotein is not yet established. However, since the concentrates contained both streptokinase and nuclease a final explanation of the cellular effect awaits further study. As mentioned previously a detailed report of the cytological studies will be the subject of an early communication.

From the results obtained in the observations on the empyemal cases there is ample evidence that nucleoprotein depolymerization and probably fibrinolysis occurred, the former by the extensive decrease in the nucleoprotein sediment and fall in viscosity, the latter by changes in the fibrin-lysing system and changes in the N.P.N. and formol titration.

Group III. Cases of hemothorax, two patients. In each, the intrathoracic blood coagulum developed following pneumonectomy.

Figures 7 and 8 illustrate changes in a case of loculated hemothorax that were brought about by the streptococcal fibrin-lysing system.

400,000 units of streptokinase were introduced into a single pocket containing 71 cc. of

BEFORE STREPTOKINASE (Note multiple fluid levels)

AFTER STREPTOKINASE (Note all loculations due to fibrinous bands have been eradicated)

Patient A. M. 20 yrs. old. Left pneumonectomy for cystic bronchiectasis. Postoperative course complicated by persistent fever and loculated hemothorax preventing aspiration of contents and subsequent thoracoplasty. 400,000 units streptokinase were introduced intrapleurally into small pocket. In 24 hours, chemical methods (chest fluid volume determinations) indicated conversion of small pocket into a single large cavity. In next two days 1,300 cc. of sanguinous fluid were removed readily from one site, and X-ray revealed that pockets were gone. Thoracoplasty followed shortly with good results.

FIG. 8. THE EFFECT OF TWO INTRAPLEURAL INJECTIONS OF STREPTOCOCCAL CONCENTRATE IN A CASE OF POST-OPERATIVE HEMOTHORAX ON THE CHEST FLUID VOLUME, FREE STREPTOKINASE, ACTIVE AND ACTIVATABLE FIBRIN-LYSING SYSTEMS, ANTISTREPTOKINASE, AND TRYPSIN INHIBITOR OF THE CHEST FLUID

400,000 units of streptokinase were given in injection 1, and 200,000 units in injection 2.

The striking clinical change is described in the text, and seen in the accompanying X-rays (Figure 7).

fluid. The concentration in this isolated area was, therefore, 5,600 units/cc. before resolution of the loculating bands took place.

The legend under Figure 7 gives the essential details of the findings in this patient both before and after the introduction of streptococcal concentrate and illustrates objectively the fibrinolytic

effect. In this instance the postoperative coagulum prevented drainage of the intrathoracic contents. However, after dissolution of the fibrinous bands and a considerable amount of the associated blood clot it was possible during the ensuing 48 hours to drain by thoracentesis a large proportion of the hemothorax which had become liquefied.

The multilocular condition had been transformed into a unilocular state. It seems likely that the fibrinolytic system was chiefly operative.

It is of special interest to note that this patient had a high titre of antifibrinolysin (antistreptokinase) at the beginning of the study. Although not proved by cultures it seems likely that he had previously had one or more infections with hemolytic streptococci since the height of antibody titre is consonant with that previously found in patients convalescent from known infection with hemolytic streptococci.

In spite of the presence of immune bodies, however, impairment of the action of the streptococcal product was not apparent. It is not possible at the present time to offer an explanation of these findings. However, the possibilities suggest themselves either that a sufficient amount of streptokinase was injected to bind with antibody and leave an excess, or that the active lysing system was put in operation before the antibody took effect. Further study of this phase of the problem is required. Also evident from the data, as in the results with the previous cases, is the fall in the activatable fibrin-lysing system coincident with the appearance of an active fibrin-lysing system, and its slow return toward the control value. Trypsin inhibitor did not change despite the activation and rapid inactivation of the fibrin-lysing system.

The course in the patient just described appears to represent an example of a beneficial therapeutic result effected by the action of the streptococcal fibrin-lysing system.

The second patient with postoperative hemothorax will be referred to only briefly since he is still under observation. Thirty-two days postoperatively the patient was transferred to our Service because it was impossible to obtain more than a few cubic centimeters of fluid from the postoperative side of the thorax. X-ray examination revealed a large shadow with fluid levels occupying approximately one-half of the thoracic cavity. From three aspirations at different sites a total of 3 cc. was obtained. Into each of the sites streptokinase was injected up to a total of 250,000 units. In the preparation of concentrate employed in this case almost all of the nuclease had been eliminated. Consequently only the fibrinolytic system was operative to any significant

degree. Twenty-four hours later 600 cc. of thin brownish fluid were removed by thoracentesis from a single site without difficulty. Immediately after the aspiration, by fluoroscopy and X-ray, only a small amount of effusion remained. Although fluid reaccumulated over the next few days, successful aspirations were readily performed indicating a considerable reduction in the presence of loculation, and the creation of a favorable situation for further intercostal drainage.

DISCUSSION

A group of unique enzymatic activities have been utilized to produce changes in fibrinous, purulent and sanguinous exudations within the pleural cavities of patients. Thus through the mediation of substances elaborated by hemolytic streptococci, fibrin is caused to undergo lysis; fibrinogen is altered so that it no longer can assume the solid form of fibrin; and the coarse sediment of purulent exudate (primarily desoxyribose nucleoprotein) is degraded to a thin solution.

Once it had been well established by detailed preliminary observations that the methods of purification of the streptococcal products developed extensively by Christensen (1) yielded preparations that were progressively less toxic, although maintaining constant or increased potency, a demonstration of the occurrence and degree of action in patients of the active principles—streptokinase and desoxyribose nuclease—became a center of interest. For this purpose quantitative estimations were made of the results of the action of each enzymatic system on its respective substrate in the areas of disease. The rapidity of the beginning of action, and the duration of continuing action after a single, and in some instances after a second injection, were determined.

Definitive enzymatic changes of a significant degree were regularly obtained and were demonstrable within an hour after the injection and endured for several days before the effect subsided and disappeared. The phenomenon was a self-limiting one following each injection.

The clinical courses of the patients have been followed by frequent physical, laboratory, and X-ray examinations over extended periods. Following the injections a febrile response occurred

not infrequently and there was also evidence of local irritation. Both signs of reaction were, however, transient.

Since the periods, in which the action of the concentrates was operative, were limited to a few days, striking evidence of favorable alterations of a permanent nature was not expected nor definitely demonstrated except for the results obtained in cases of loculated hemothorax, one example of which is described in detail, and in some of the instances of empyema. In patients with hemothorax, it is obvious that consideration must be given to the broad principles and problems of thoracic surgery before the application of the procedure may be most advantageously made.

The findings, however, constitute a background against which the scope of the study is being broadened to include a consideration of the possible usefulness of the procedure when utilized under appropriate circumstances. The desirability of causing the liquefaction of fibrin or of preventing its formation, or of resolving purulent nucleoprotein containing sediments, would on theoretical grounds depend upon a variety of conditions associated with the pathogenesis and expected evolution of the disease processes to which this method involving lytic activities might be applied. Comparable principles would also be applicable to exudative diseases involving locations in the body other than the pleural area.

If the solid increments constitute part of an advantageous walling off process then the liquefaction of the wall might promote a spread of the infection in its acute phases before the patients' immunity was sufficient to restrain the dissemination of the infection. On the other hand, the same walling off may prevent the introduction of antibacterial reagents of an immunological nature, as well as antibiotic substances, into the field of disease. Under the latter circumstances elimination of the wall might be advantageous. Other sets of conditions concern factors that are involved in the ultimate formation of scar tissue, or of adhesions, and the permanent thickenings that are related to the final organization of infected areas.

The results presented in this article serve as a basis for extending the study along the lines that have been discussed.

SUMMARY

1. Twenty-three patients suffering from exudative pleuritis associated with different types of diseases have received intrapleural injections of partially purified concentrates containing streptococcal fibrinolysin (streptokinase) and desoxyribose nuclease.

2. Intrapleural fibrinolytic and proteolytic changes due to the activity of the fibrin-lysing system were demonstrable in samples of the exudates taken at repeated intervals after the injection. The effects were self-limiting after each injection.

Intrapleural depolymerization of the nucleoprotein of the solid sediment of the exudates was also demonstrable in a similar manner.

3. When toxic manifestations occurred following the injections, they were limited to transient febrile reactions with general malaise, and a local outpouring of leucocytes of a few days' duration.

4. The possibility is discussed of influencing favorably by the enzymatic systems the course of exudative types of diseases and it is being given additional study.

The authors wish to acknowledge the excellence of the technical assistance which they have received from Miss Harriet Heffernan, Mr. John Goeller, and Miss Doris Bitz.

THE BEHAVIOR OF RADIOIODINE IN THE BLOOD¹

By WILLIAM M. McCONAHEY,² F. RAYMOND KEATING, JR.,
AND MARSCHELLE H. POWER

(From the Divisions of Medicine and Biochemistry, Mayo Clinic, Rochester, Minnesota)

(Received for publication July 10, 1948)

Radioiodine has been used to study the function of the human thyroid gland in various ways. The quantity of radioiodine collected by the thyroid has been determined directly by *in vivo* measurements (Hamilton, Soley and co-workers [1-4]; Hertz and co-workers [5]), and indirectly by estimations from the total quantity excreted in the urine over a fixed period (Hertz and co-workers [5]; Rawson and co-workers [6, 7]). The distribution of iodine in the thyroid has been studied by autoradiograms (3) or by chemical analysis of excised tissue (5). Most recently the capacity of the thyroid to concentrate radioiodide has been studied by Stanley and Astwood (8) after previous administration of an antithyroid drug such as mercaptopinidazol.

Keating, Power, Berkson, and Haines (9) have employed radioiodine to investigate the kinetics of iodine metabolism. They studied the urinary excretion of radioiodine by collecting all the urine in short periods for three days or longer. By plotting cumulative urinary excretion against time, they obtained an exponential curve from which were estimated four quantities: (1) a renal fraction (that part of the dose of radioiodine primarily excreted in the urine); (2) a disappearance rate (which they inferred to represent the proportional rate of disappearance of radioiodine from the blood); (3) a renal excretion rate (the proportional rate of excretion into the urine); and (4) a so-called collection rate (the proportional rate of disappearance into other sites than the kidneys, of which the most important is the thyroid). The most significant measure of thyroid activity was the collection rate, which was much less than normal in hypothyroid

patients and much greater than normal in hyperthyroid patients.

The present study was undertaken as an extension of the foregoing observations. Its objects were (1) to examine directly the behavior of radioiodine in blood after its oral administration to persons who had varying states of thyroid function; (2) to compare the disappearance rate of radioiodine in blood as determined directly from observations in the blood itself with estimates of this same value obtained from urinary studies in the manner previously described; and (3) to examine the appearance in the blood of organically bound radioiodine.

PROCEDURES

The subjects selected for study came to the laboratory without breakfast. After withdrawal of a control sample of blood, radioiodine (I^{131} , Oak Ridge Laboratories, A. E. C.), in the form of sodium iodide dissolved in about 150 cc. of water containing 100 μ g. of nonradioactive sodium iodide, was given by mouth. Samples of blood and urine were thereafter collected at stated intervals. The quantity of radioiodine present in these specimens was estimated by means of a Geiger-Müller counting tube with thin mica window in connection with a suitable scaling circuit. All counts were corrected for "background," which was uniformly about 0.5 count per second or less. Appropriate aliquots of each dose given were reserved as standards, each of which was counted simultaneously with its corresponding blood and urine samples. The method of preparing urine for counting has been described (Keating and co-workers [9]). The blood samples were allowed to clot at room temperature and, after the separation of the serum by centrifugation, were analyzed for radioactivity as described in the next section.

Total radioactivity of serum. The counting of films of serum dried directly on thin copper disks was unsatisfactory. However, after partial alkaline hydrolysis dry films suitable for counting could be obtained. One cc. of serum in a pyrex test tube 7 mm. (internal diameter) by 100 mm. was thoroughly mixed with 0.100 cc. of 2.5 N solution of sodium hydroxide. The tube was covered with a small pyrex cup and heated for 30 minutes at 10 to 15 pounds in a pressure cooker. This treatment caused little or no change in volume. Some sediment which

² Fellow in Medicine, Mayo Foundation.

formed was carefully resuspended by shaking, although later studies showed that little or no error was introduced by failure to resuspend this sediment. Samples of the alkaline digest were measured out for radioactivity analysis, by means of a syringe pipet calibrated to deliver 0.200 cc. In order to prevent accumulation of radioiodine in this pipet, which might then cause error in future samples, it was rinsed between measurements with 10 portions of strong solution of potassium iodide followed by 10 portions of water. Finally two portions of the digest to be examined were drawn in and discarded, then duplicate 0.200 cc. samples were transferred to copper disks 1 inch (2.5 cm.) in diameter. The samples were dried slowly under an infra-red lamp, cooled, and counted immediately thereafter, in order to avoid variations attendant on the possible absorption of moisture by the dry alkaline films. The counts observed, corrected for background as mentioned previously, were converted to counts per second per unit volume and, by reference to the simultaneously counted standard, to percentage of administered dose per liter of serum. Each planchet was counted at least twice, and usually enough counts were taken so that the variation due to randomness of atomic disintegration would be less than 5 per cent. Finally, a positive correction of 15 per cent was applied to all counts of serum digests, to compensate for losses due to "absorption" of beta rays by the deposit of alkali and partly degraded protein.

This correction factor was obtained as follows: To 34 samples of normal serum, each measuring 0.9 cc., were added 0.1 cc. of radioiodine of known radioactivity and 0.1 cc. of 10 per cent sodium hydroxide. The samples were heated in a pressure cooker and 0.2 cc. aliquots were prepared for dry counting on planchets as described previously. These were compared with planchets prepared from equal amounts of radioiodine in aqueous solution as standards. It was found that in the 34 samples, the mean loss of radioactivity by absorption was 15.2 ± 0.5 per cent with a range of 11.1 to 20.0 per cent.

In order to investigate the reproducibility of the method, blood was drawn from a hyperthyroid patient 24 hours after administration of 100 microcuries of I^{131} . Ten samples of the serum, each of 1.0 cc., were analyzed for their radioactivity. The mean value obtained was 11.19 counts per second per cubic centimeter. The standard deviation for the determinations from the separate specimens of serum was 0.43 counts per second or about 4 per cent of the mean, which gives an estimate of the error of such determinations. Taking into consideration variations caused by "absorption," variations inherent in the counting equipment and errors introduced by chemical manipulation, it is estimated that the over-all experimental error of a single determination of radioiodine did not exceed 10 to 15 per cent.

Radioiodine precipitated from serum by protein precipitants. This fraction, henceforth referred to as "precipitable" radioiodine, was separated by means of precipitation of proteins with the zinc sulfate-sodium hydroxide reagents of Somogyi (10, 11), as used by Man, Smirnow, Gildea and Peters (12) in their study

of serum iodine fractions. In this procedure, 1 cc. of serum in a 15 cc. pyrex centrifuge tube calibrated in tenths was treated with 1.00 cc. of 0.75 N solution of sodium hydroxide and 8.00 cc. of 0.125 per cent zinc sulfate in 0.031 N solution of sulfuric acid. The mixture was stirred thoroughly with a thin glass rod and centrifuged for five minutes at 1,500 r.p.m., and the supernatant was removed by decantation. The tube was filled with distilled water, the protein precipitate was thoroughly dispersed by stirring with the glass rod and the tube was again centrifuged. The supernatant was again discarded and the washing procedure was repeated twice more. The precipitate was next dispersed by stirring with 0.50 cc. of 2.5 N sodium hydroxide. The stirring rod was rinsed with two drops of water, and the alkaline mixture was autoclaved as in the determination of total radioiodine. After removal of the tube from the cooker, the volume of the digest was noted, and 0.200 cc. samples were measured out, dried and counted, as previously described. "Absorption" losses in this method of determining serum precipitable radioiodine were about the same as those noted in the determination of total radioactivity (actually the mean loss of 15 samples was 15.7 ± 0.6 per cent). Control experiments in which radioiodine was added to serum showed that all but 0.25 to 2.9 per cent of added radioactivity was removed by the precipitation and washing technic.

An estimate of the error of the method for serum precipitable radioiodine was obtained in the following manner: ten 1.0 cc. samples of serum from blood which had been withdrawn from a hyperthyroid patient 24 hours after oral ingestion of a tracer dose were analyzed for serum precipitable radioiodine. The mean value obtained was 2.13 counts per second per cubic centimeter and the standard deviation for the determination from the separate serum specimens was 0.36 counts per second or about 17 per cent of the mean.

Miller and associates (13) found that exchange occurred *in vitro* between inorganic and organic iodine compounds under certain conditions of pH and temperature. The possibility that similar exchange might account for some of the precipitable radioiodine observed with the method which we employed was investigated in the following manner. Radioiodine as iodide was added to each of eight tubes containing 1.0 cc. of normal human serum. Four tubes were stored at room temperature, and four were incubated at body temperature. One specimen from each group was analyzed for serum precipitable radioiodine after four, six, eight and 13 days, respectively. The quantity of radioiodine remaining in the precipitable fraction after washing was negligible (0.2 to 1.5 per cent of the total radioiodine present in the whole serum). On the basis of these observations it was felt that exchange could not account for any significant proportion of the precipitable radioiodine observed.

Thirty-one persons who had various thyroid conditions consented to be studied; 28 of these were patients being treated for thyroid disease and three were normal subjects. Serial blood levels of total radioiodine were determined in all 31 persons. Table I shows the functional

state of the thyroid and basal metabolic rates of the patients studied. Seventeen had hyperthyroidism, nine were euthyroid and six had myxedema. One patient who had carcinoma of the thyroid was studied twice—once while his thyroid function was normal and later while myxedema was present as a result of a "thyroidectomizing dose" of I^{131} . By a euthyroid person is meant one whose tissues at large receive the normal amount of thyroid hormone daily irrespective of the anatomic state of the thyroid gland.

Of the 36 doses of I^{131} given, 21 were tracer and 15 were therapeutic doses. The tracer dose used in most cases was 100 microcuries, although a few patients received more. A therapeutic dose is here defined as one large enough to destroy thyroid tissue by radiation. Comparison of tracer doses with subsequent therapeutic doses in the same patient did not disclose consistent or significant differences which could be ascribed to radiation effect within the 48-hour period when most observations were made. This does not exclude the possibility that radiation effects may have been present in either the tracer or the therapeutic doses, but it appears reasonable to assume that any effects of radiation present in the data are of small magnitude.

The use of 100 μ g. of sodium iodide as carrier in these studies theoretically introduces an error in the tracer character of the experiments. It may be calculated that in the average person this quantity of iodide in equilibrium with the blood and extracellular fluids represents an initial increase in the concentration of iodide of the order of 0.5 μ g. per 100 cc. of plasma. We have compared studies conducted with 100 μ g. of carrier with studies employing carrier-free radioiodide as well as

studies involving a carrier of 1 to 10 μ g. Such observations indicate that the use of 100 μ g. of sodium iodide as carrier does not affect the results observed either qualitatively or quantitatively to any significant degree.

RESULTS

Total radioiodine in blood serum. Radioiodine appeared in the circulating blood within a few minutes after oral administration. The concentration of radioiodine rose rapidly and reached a maximal level within one-half to one and one-half hours after ingestion, the time at which the

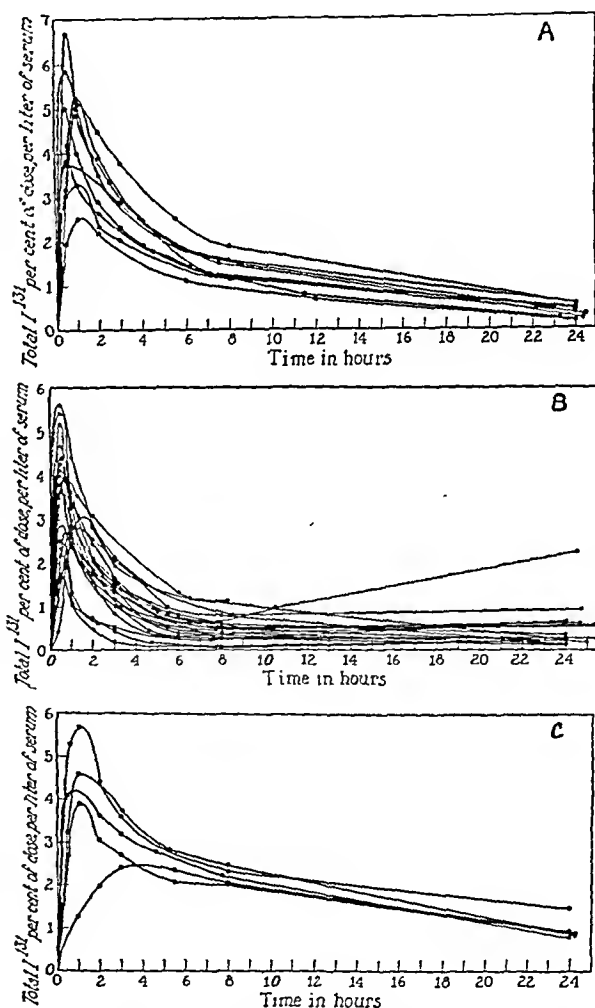

FIG. 1. THE CONCENTRATION OF TOTAL RADIOIODINE IN THE SERUM OF PERSONS WHO HAD (A) NORMAL THYROID FUNCTION, (B) HYPERTHYROIDISM AND (C) MYXEDEMA

The group who had normal thyroid function includes three normal persons, four patients who had adenomatous goiter without hyperthyroidism, and two patients who had low grade nonfunctioning carcinomas of the thyroid.

maximum level was attained varying somewhat with the functional state of the thyroid. Thereafter, the concentration diminished at a rate which was related to the functional state of the thyroid. Figure 1 shows the individual curves for the concentration of radioiodine in serum during the first 24 hours in all cases of the three groups studied. Figure 2 shows average curves for each of the three groups. In euthyroid patients, the concentration of radioiodine in the blood reached a maximal level between one-half and one hour and then fell for the rest of the 24 hours. In hyperthyroid patients, the concentration reached a maximal level sooner, usually in about one-half hour, then fell more rapidly than in the normals for six or eight hours, and thereafter decreased very slowly in some cases, leveled off in others, and in a considerable number again rose a second time from the low value observed at about eight hours after the dose. In patients who had hypothyroidism, a maximal level was reached later, usually between one, and one and one-half hours, and the level thereafter diminished more gradually than in euthyroid persons. Since, as is well known, both hyperthyroidism and myxedema affect the volume of both plasma and extracellular fluid, it is apparent that these data must be modified to some extent by such factors. Accurate evaluation of these factors would be possible only if both blood volume and volume of extracellular fluid had been measured in each individual case, a procedure which we were unable to follow in this study. Fortunately it appears probable that

changes in blood volume and the volume of extracellular fluid accompanying various levels of thyroid activity were relatively minor factors in the differences which we observed.

Serum precipitable radioiodine. Levels of precipitable radioiodine in serum were determined in 13 cases (nine hyperthyroid, one myxedematous, and three euthyroid patients). Since it was not possible with the technics employed to measure precipitable radioiodine in the blood with accuracy after the administration of a small tracer dose, only persons who had received larger doses of radioiodine were studied in this manner. The doses of I^{131} administered ranged from 1 to 100 millicuries. The results of this portion of the study may, therefore, have been affected by the consequences of radiation, but one may be justified in assuming that the results observed corre-

spond at least qualitatively to physiologic conditions.

Figure 3A shows the values for serum precipitable radioiodine plotted as percentage of dose per liter of serum for a case of hyperthyroidism. The curve of total radioiodine in the serum is broken into two fractions: the one of serum precipitable radioiodine and the other of inorganic radioiodide obtained by subtracting values for precipitable radioiodine from total radioiodine. In Figure 3B are plotted the corresponding data in a patient who had normal thyroid function. Serum precipitable iodine appeared more rapidly and in larger concentrations in the hyperthyroid patient than in euthyroid persons and this fact appears to account for the leveling off or for the secondary rise in the curve of total radioiodine in serum observed in hyperthyroid cases. Figure 3C shows total radioiodine concentration and the inorganic and serum precipitable fractions, in a myxedematous patient. Inorganic iodide falls more slowly and precipitable iodine reaches a smaller concentration than in normal persons. In hyperthyroid subjects apparently all of the circulating radioiodine was precipitable after a period which averaged about 48 hours (Figure 4). In euthyroid subjects the average time re-

quired for all circulating radioiodine to become precipitable was about 96 hours, and in the myxedematous subject this time was 290 hours. The foregoing results do not preclude the possibility that a small inorganic fraction might persist in any case for a longer time since the method employed for measuring precipitable radioiodine was relatively insensitive.

COMMENT

Figure 1 shows considerable variability of the curves of total radioiodine concentration in serum during the first six hours. Overlapping by members of the different groups is at a minimum at eight hours. In myxedema the concentration of radioiodine exceeded 2 per cent of the dose per liter of serum (from 2 to 2.5 per cent) at eight hours. The euthyroid and hyperthyroid curves overlapped a little at this time (1 to 1.9 per cent and 0.05 to 1.2 per cent, respectively), but the curves of neither group overlapped those of the cases of myxedema. Only one of the euthyroid curves was less than 1.2 per cent and only two of the hyperthyroid curves were more than 1 per cent.

Examination of the curve of concentration of total radioiodine in serum during the first 24 hours discloses at least three components: (1) a rapid rise to a maximal concentration and a brief, rapid fall; (2) a more prolonged fall at an exponential rate, and (3) a continued but much slower fall (or sometimes, in case of hyperthyroidism, a secondary slow rise to a higher level). Component 1 appears to reflect absorption from the gastro-intestinal tract and establishment of equilibrium between the blood and the body fluids; component 2 represents the disappearance of radioiodine as inorganic iodide from the blood and the body fluids into the urine, the thyroid and other sites of disposal; component 3 reflects in part the appearance in the blood of precipitable (that is, organically bound) radioiodine.

Keating and co-workers estimated the disappearance rate of radioiodine from the blood from the curve of excretion in the urine. The disappearance rate can be determined directly from the second component of the concentration curve of radioiodine in the blood. When the logarithm of

FIG. 4. SERUM PRECIPITABLE RADIOIODINE IN VARIOUS STATES OF THYROID FUNCTION

Each curve is constructed from the mean values of the cases comprising the group versus time; the value expressed is the percentage of the total radioiodine in serum which is precipitable. (From McConehey, W. M., Keating, F. R., Jr., and Power, M. H., The behavior of radioiodine in the blood in various thyroid states. *Tr. Am. A. Study of Goiter* [In press].)

concentration is plotted against time, the observations fit a straight line, the slope of which is the rate of disappearance of radioiodine from the blood.

The observations comprising component 3 fall above this straight line and in some hyperthyroid cases the period during which concentration of total radioiodine in blood fits an exponential function is rather short. If instead one plots the logarithm of inorganic radioiodine (estimated by difference as described) as ordinate, with time as abscissa, the points continue to fit an exponential function for a much longer period. This fact suggests that it is the inorganic iodide which disappears at an exponential rate and that it is the appearance of organically bound iodine which causes the curve of total radioiodine to deviate from an exponential curve.

* P values obtained from Table of T. R. A. Fisher, *Statistical Methods for Research Workers*, Seventh Edition, Oliver and Boyd, 1938.

† The values given are the means and standard errors of the means.

In Table II the mean disappearance rates of radioiodine from blood for each group, calculated directly from observations on the blood, are compared with the values obtained from simultaneous observations on the urine of each subject calculated in the manner described by Keating and co-workers. The means of the individual differences, which are also given, do not appear to be significant, and may reflect merely the errors of the methods employed. It seems, therefore, that the disappearance rate of radioiodine from blood measured by either method reflects variations in thyroidal function with respect to iodine collection. However, since radioiodine disappears from

blood into the urine, and also into other tissues in addition to the thyroid, disappearance rate is not a direct or quantitative measure of thyroidal accumulation of iodine. This is evidenced by the values for disappearance rate in cases of myxedema, in most of which accumulation of radioiodine by the thyroid was found by *in vivo* measurements to be negligible or absent.

The appearance of precipitable radioiodine in blood can be construed as largely representing radioiodine collected by the thyroid, synthesized into organic compounds and secreted into the circulation. Determinations of precipitable radioiodine reflect variations in thyroid function in several ways: 1. The concentrations of precipitable radioiodine reached in cases of hyperthyroidism are greater than in cases of euthyroidism. 2. Precipitable radioiodine can be detected sooner in hyperthyroid cases than in euthyroid cases and the concentration increases at a more rapid rate. 3. Estimation of precipitable radioiodine as a percentage of total serum radioiodine reflects both the foregoing and the differences in the behavior of inorganic iodide with variations in thyroidal function, so that precipitable radioiodine replaces the inorganic fraction much more rapidly than normal in hyperthyroid subjects and much less rapidly than normal in hypothyroid subjects. These relationships are entirely consistent with what is known about the behavior of chemically determined precipitable iodine in persons who have varying states of thyroidal activity.

It is surprising and a little disturbing to note the appearance of precipitable radioiodine in the single case of myxedema in which this determination was made (Figures 3C and 4). The patient was a young man having carcinoma of the thyroid who some months previously had been made myxedematous by means of a "thyroidec-tonizing" dose of radioiodine. The concentration of precipitable radioiodine observed in this case was small, and this concentration was substantially achieved within a few hours (Figure 3C). The survival of some thyroid tissue cannot be excluded, although no detectable collection occurred in the thyroid region and the basal metabolic rate was -25 per cent. The possibility of *in vivo* exchange occurring in the blood remains a remote possibility but such exchange could not

be demonstrated *in vitro*. The observations of precipitable radioiodine in this case may be of some interest in connection with the demonstration by Chapman (14) and by Morton and associates (15) that iodine may be organically combined elsewhere in the body than in the thyroid.

The method employed here to estimate concentration of precipitable radioiodine is relatively insensitive and relatively inaccurate. On this account and because of the possibility of distortion by the quantities of radiation involved it appears unwise to attempt to analyze quantitatively the kinetic behavior of organically bound radioiodine from these data. It appears likely, however, that with more sensitive and accurate methods of analysis the rate of increase of organically bound radioiodine in blood and the maximal concentration achieved can be compared with the concentration of protein-bound iodine measured by chemical methods in order to obtain a measure of turnover rate of protein-bound iodine.

SUMMARY AND CONCLUSIONS

1. Levels of total radioiodine in the blood after oral ingestion of I^{131} in the form of iodide show significant differences in various thyroid states. Eight hours after ingestion, mean concentration of radioiodine in the serum was 2.06 per cent of the dose per liter in cases of myxedema, 1.28 per cent in euthyroid persons and 0.49 per cent in cases of hyperthyroidism.

2. The curve of total radioiodine in serum plotted against time has three components: (a) an initial rapid increase followed by a brief, rapid fall, regarded as reflecting gastro-intestinal absorption and equilibration with body fluids; (b) an exponential fall, regarded as reflecting disappearance of radioiodine as iodide from the blood into the thyroid, the urine and other sites of disposal, and (c) a third phase which indicates the appearance in the blood of organically bound radioiodine.

3. The rate of disappearance of radioiodine from the blood reflects variations in thyroidal function, being more rapid than normal in hyperthyroid subjects and less rapid than normal in hypothyroid ones.

4. Comparison of the rate of disappearance of radioiodine from blood estimated directly from

blood itself with estimations of the same rate determined from simultaneous observations of urinary excretion of radioiodine did not disclose any significant difference. The latter method therefore appears to be an appropriate means of estimating the disappearance rate of radioiodine from blood.

5. Precipitable radioiodine appeared in the blood much sooner, rose more rapidly and reached higher concentrations in hyperthyroid than in euthyroid persons. A small concentration of precipitable radioiodine was observed in a patient who had myxedema.

* P values obtained from Table of T. R. A. Fisher, *Statistical Methods for Research Workers*, Seventh Edition, Oliver and Boyd, 1938.

† The values given are the means and standard errors of the means.

In Table II the mean disappearance rates of radioiodine from blood for each group, calculated directly from observations on the blood, are compared with the values obtained from simultaneous observations on the urine of each subject calculated in the manner described by Keating and co-workers. The means of the individual differences, which are also given, do not appear to be significant, and may reflect merely the errors of the methods employed. It seems, therefore, that the disappearance rate of radioiodine from blood measured by either method reflects variations in thyroidal function with respect to iodine collection. However, since radioiodine disappears from

blood into the urine, and also into other tissues in addition to the thyroid, disappearance rate is not a direct or quantitative measure of thyroidal accumulation of iodine. This is evidenced by the values for disappearance rate in cases of myxedema, in most of which accumulation of radioiodine by the thyroid was found by *in vivo* measurements to be negligible or absent.

The appearance of precipitable radioiodine in blood can be construed as largely representing radioiodine collected by the thyroid, synthesized into organic compounds and secreted into the circulation. Determinations of precipitable radioiodine reflect variations in thyroid function in several ways: 1. The concentrations of precipitable radioiodine reached in cases of hyperthyroidism are greater than in cases of euthyroidism. 2. Precipitable radioiodine can be detected sooner in hyperthyroid cases than in euthyroid cases and the concentration increases at a more rapid rate. 3. Estimation of precipitable radioiodine as a percentage of total serum radioiodine reflects both the foregoing and the differences in the behavior of inorganic iodide with variations in thyroidal function, so that precipitable radioiodine replaces the inorganic fraction much more rapidly than normal in hyperthyroid subjects and much less rapidly than normal in hypothyroid subjects. These relationships are entirely consistent with what is known about the behavior of chemically determined precipitable iodine in persons who have varying states of thyroidal activity.

It is surprising and a little disturbing to note the appearance of precipitable radioiodine in the single case of myxedema in which this determination was made (Figures 3C and 4). The patient was a young man having carcinoma of the thyroid who some months previously had been made myxedematous by means of a "thyroidec-tomizing" dose of radioiodine. The concentration of precipitable radioiodine observed in this case was small, and this concentration was substantially achieved within a few hours (Figure 3C). The survival of some thyroid tissue cannot be excluded, although no detectable collection occurred in the thyroid region and the basal metabolic rate was -25 per cent. The possibility of *in vivo* exchange occurring in the blood remains a remote possibility but such exchange could not

be demonstrated *in vitro*. The observations of precipitable radioiodine in this case may be of some interest in connection with the demonstration by Chapman (14) and by Morton and associates (15) that iodine may be organically combined elsewhere in the body than in the thyroid.

The method employed here to estimate concentration of precipitable radioiodine is relatively insensitive and relatively inaccurate. On this account and because of the possibility of distortion by the quantities of radiation involved it appears unwise to attempt to analyze quantitatively the kinetic behavior of organically bound radioiodine from these data. It appears likely, however, that with more sensitive and accurate methods of analysis the rate of increase of organically bound radioiodine in blood and the maximal concentration achieved can be compared with the concentration of protein-bound iodine measured by chemical methods in order to obtain a measure of turnover rate of protein-bound iodine.

SUMMARY AND CONCLUSIONS

1. Levels of total radioiodine in the blood after oral ingestion of I^{131} in the form of iodide show significant differences in various thyroid states. Eight hours after ingestion, mean concentration of radioiodine in the serum was 2.06 per cent of the dose per liter in cases of myxedema, 1.28 per cent in euthyroid persons and 0.49 per cent in cases of hyperthyroidism.

2. The curve of total radioiodine in serum plotted against time has three components: (a) an initial rapid increase followed by a brief, rapid fall, regarded as reflecting gastro-intestinal absorption and equilibration with body fluids; (b) an exponential fall, regarded as reflecting disappearance of radioiodine as iodide from the blood into the thyroid, the urine and other sites of disposal, and (c) a third phase which indicates the appearance in the blood of organically bound radioiodine.

3. The rate of disappearance of radioiodine from the blood reflects variations in thyroidal function, being more rapid than normal in hyperthyroid subjects and less rapid than normal in hypothyroid ones.

4. Comparison of the rate of disappearance of radioiodine from blood estimated directly from

blood itself with estimations of the same rate determined from simultaneous observations of urinary excretion of radioiodine did not disclose any significant difference. The latter method therefore appears to be an appropriate means of estimating the disappearance rate of radioiodine from blood.

5. Precipitable radioiodine appeared in the blood much sooner, rose more rapidly and reached higher concentrations in hyperthyroid than in euthyroid persons. A small concentration of precipitable radioiodine was observed in a patient who had myxedema.

INDUCED INSULIN RESISTANCE IN THE RABBIT¹

By FRANCIS C. LOWELL AND WILLIAM FRANKLIN

(From the Evans Memorial and Massachusetts Memorial Hospitals and the Department of Medicine, Boston University School of Medicine, Boston)

(Received for publication July 27, 1948)

A high degree of resistance to insulin occasionally develops in patients receiving repeated injections of insulin. This occurs most frequently in patients with diabetes, but non-diabetic individuals receiving insulin shock therapy for psychiatric disorders may also develop insulin resistance unassociated with any other demonstrable disturbance in carbohydrate metabolism. An immune mechanism has been repeatedly suggested as one underlying cause, a view for which strong evidence was obtained in the study of a case of insulin resistance in this laboratory (1-3). Resistance developed during the administration of insulin at the end of three insulin-free periods of three to five months, suggesting an immune response to the injected insulin. Furthermore, the resistance appeared to be species-specific as indicated by absence of resistance to human insulin at a time when resistance to commercial (beef and pork) insulin was clearly present. These observations prompted the study reported herein.

MATERIALS AND METHODS

Twenty-four adult rabbits of various breeds were injected subcutaneously according to a schedule similar to that shown in Table I for the fifth animal in the series. The injection mixture was made as follows: 1) Two parts of an insulin solution containing 250 u/ml. with 0.5% phenol, 2) Three parts of Falba² and 3) Five parts of mineral oil containing 5 mg. dry, heat-killed *M. butyricum* per ml.³ The insulin and Falba were thoroughly mixed with an electric stirrer and the mineral oil containing the acid-fast organisms was then added and likewise thoroughly mixed. Each milliliter of the final mixture contained 50 u of insulin. Preliminary tests showed that the injection of more than 50 u into rabbits often caused severe hypoglycemic symptoms or death. Masses of various sizes and consistencies appeared at the injected sites and in some instances drained

purulent material. Before receiving the insulin-adjuvant mixture, some animals were injected intravenously in the fasting state with 0.1 u crystalline insulin per kilogram in order to test the responsiveness to insulin. In every instance in which this was done, a definite but brief fall in blood sugar occurred. Blood sugar determinations using 0.2 ml. of blood were done with the micro-method described by Nelson (4), using the Folin method of precipitation (5). Blood was obtained from the ear veins with a No. 26 hypodermic needle and a dry tuberculin syringe. The animals were not tied down or otherwise forcibly held. Struggling could be avoided in most instances by infiltrating the area around the vein with novocaine. Insulin tolerance tests with 0.1 u/kg. were repeated at intervals of five to ten weeks and further injections of the insulin-adjuvant mixture were given according to a schedule similar to that shown in Table I. The human insulin used in these experiments was prepared in the summer of 1947 from human pancreas obtained from two to 27 hours post-mortem with a method modified after Somogyi (6). The material was sterilized by passage through a Seitz filter and phenol was added to make a final concentration of 0.5%. Assay in mice and rabbits indicated that each milliliter contained 24 ± 2 u/ml. The details of the preparation and assay of the human insulin are given elsewhere (7).

RESULTS

Of the 24 animals injected with the insulin-adjuvant mixture, four became insulin-resistant. One of these animals, the first to become resistant, has been studied in detail and forms the subject of this report. One of the other resistant animals died of causes apparently unrelated to the experimental procedure, and the remaining two appear to be in good health. Of the 20 rabbits which failed to become resistant, nine died within six months of starting immunization. Ten animals have received injections of the adjuvant mixture for eight months or more without becoming resistant.

The fifth rabbit in our series developed clear-cut resistance to insulin three months after injections of the insulin-adjuvant mixture were begun. All the procedures carried out in this animal are shown in Table I. The number of tests performed was limited by the tendency of the ear

veins to become thrombosed after continued use, though care was taken to avoid this. Some of the insulin tolerance tests shown in Table I are irregular, as for example those done on 10/15/47, 11/4/47 and 11/19/47. These irregularities may

be due to undetected errors in technic but the data clearly indicate the development of a high degree of resistance to crystalline insulin. In this animal, a dose of 0.1 u/kg. crystalline insulin intravenously had caused a fall of 20 mg./100 ml.

INTRAVENOUS INSULIN TOLERANCE TESTS IN THE RESISTANT RABBIT
AND IN NORMAL AND UNSUCCESSFULLY IMMUNIZED RABBITS

FIG. 1

The dates on which the insulin tolerance tests in the resistant rabbit were done were as follows:

0.4 u/kg. I. V. 9/23/47. This test is also shown in Figure 3.

0.5 u/kg. I. V. 1/6/48. This test is also shown in Figures 3 and 5.

in the blood sugar before any injections of the adjuvant mixture were given and a similar fall followed the same dose of insulin six weeks after these injections were begun. After three or more months, four or five times this dose (0.4 u/kg. and 0.5 u/kg.) given intravenously caused a fall of 21 mg./100 ml. or less as shown in the two upper curves of Figure 1. The blood sugars of two normal rabbits receiving 0.5 u/kg. fell 40 mg./100 ml. and 60 mg./100 ml., respectively, and in two other animals, which received the adjuvant mixture but failed to become resistant, marked falls in blood sugar followed the injection of 0.3 u/kg. Further tests done in the resistant animal are shown in Figure 2 where it may be seen that a large dose of insulin (4.4 u/kg.) was required to produce a moderate fall in blood sugar. Two of the tests shown in Figure 2 were done without fasting in order to decrease the risk of killing the animal in hypoglycemic shock, a precaution which was probably unnecessary. The curve obtained in the fasting state with 2.5 u/kg. was done at a later date than the others and we

INTRAVENOUS TOLERANCE TESTS WITH LARGE DOSES OF COMMERCIAL
INSULIN AFTER DEVELOPMENT OF RESISTANCE

FIG. 2

The dates on which the insulin tolerance tests were done were as follows:

1.6 u/kg. I. V. non-fasting 10/17/47.

2.5 u/kg. I. V. fasting 3/19/48.

4.4 u/kg. I. V. non-fasting 10/20/47.

have reason to believe, on the basis of protection studies in mice (8) with the animal's serum, that a higher degree of resistance was present at this time. These studies will be reported later.

The condition of the site at which the adjuvant mixture was injected did not appear to influence the animals' response to insulin as judged by the normal insulin tolerance curves obtained in animals with fluctuant masses or draining sinuses. Furthermore, only one of the four animals that became resistant developed any significant inflammation at the injected site, and even in this subject resistance to insulin was clearly demonstrable when the inflammation had subsided.

In none of the tolerance tests done in this animal were there any symptoms suggesting a hypoglycemic reaction or any allergic manifestations such as scratching, dyspnea, or collapse. The endermal injection of 0.02 ml. of crystalline insulin in a concentration of 4 u/ml. on two occasions caused no immediate or delayed local reaction.

The repeated finding of a normal fasting blood sugar indicated that the animal had no resistance to his own insulin. Furthermore, the animal appeared to be in good health and gained weight steadily. An intravenous glucose tolerance curve with 0.5 gm. glucose/kg. gave the following result suggesting normal carbohydrate metabolism. FBS 90 mg./100 ml.; 30 minutes, 116 mg./100 ml.; one hour, 88 mg./100 ml.; two hours, 88 mg./100 ml.; three hours, 88 mg./100 ml. In view of the presence of resistance to commercial insulin, these results indicated the presence of a species-specific immunity to beef and pork, but not to rabbit insulin.

Further evidence for the species specificity of the resistance was obtained in tests with human insulin. Curves are shown in Figure 3 where approximately 0.3 u/kg. of human insulin caused falls in blood sugar of 39 mg./100 ml. and 54 mg./100 ml., results which were similar to those obtained in normal animals receiving either human or crystalline insulin in this dosage. As

TESTS WITH ACTIVE INSULIN, CYSTEINE-INACTIVATED INSULIN AND THE
COMBINATION OF THE TWO IN NORMAL RABBITS

FIG. 4

described above, much smaller falls in blood sugar followed the injection of 0.4 u/kg. and 0.5 u/kg. of commercial insulin. The tests with human insulin were done in the period between the two tests with commercial insulin and therefore it is unlikely that the responsiveness to human insulin was due merely to the loss of a resistance which was not species-specific.

A final experiment was based on the assumption that the resistant animal's antibody was directed against antigenic determinants on the insulin molecule which were distinct from the group or groups to which the hormone owes its specific effect on carbohydrate metabolism. Accordingly, if the insulin molecule were shorn of its active group, antibody might still combine with it and the injection of a large amount of such

insulin into the resistant animal, by combining with the animal's antibody, might then bring about temporary susceptibility to the action of a relatively small dose of active insulin.

To this end, 400 u of crystalline insulin were inactivated under reduced oxygen tension with 167 mg. cysteine HCl in the presence of sufficient NaOH to bring the pH to approximately 7.0 (9). After the addition of phenol to make a final concentration of 0.5%, the solution contained the equivalent of 27 u/ml. During the procedure and upon exposure to room air the cysteine in this mixture slowly became oxidized to cystine forming a precipitate which was resuspended each time the solution was used. When tested in fasting mice, 0.5 ml. of a 1:5 dilution failed to induce any symptoms at 35° C., indicating that

INFLUENCE OF CYSTEINE-INACTIVATED INSULIN ON THE SUSCEPTIBILITY OF THE
INSULIN-RESISTANT RABBIT TO ACTIVE INSULIN

FIG. 5

The dates on which the insulin tolerance tests were done were as follows:

Active insulin 0.5 u/kg. I. V. 1/6/48.

Cysteine-inactivated insulin 15 u/kg. I. V. 1/12/48.

Cysteine-inactivated insulin followed by active insulin 1/8/48.

the insulin had been at least 99% inactivated.

The experiments with cysteine-inactivated insulin are shown in Figures 4 and 5. Each experiment consisted of three blood sugar curves done with cysteine-inactivated insulin alone, active insulin alone and cysteine-inactivated insulin followed in 20 minutes by active insulin. All injections were made intravenously. In each instance, the injection of the inactivated insulin caused a temporary rise in blood sugar which may have been due entirely or in part to the cysteine present. In the normal animals, the hypoglycemic effect of active insulin given after cysteine-inactivated insulin was like that of active insulin alone. A strikingly similar result was obtained in the resistant animal though active insulin alone caused only a slight fall in blood sugar. Thus, two agents—one of which lacked blood sugar lowering activity and indeed tended to raise the blood sugar, and the other having only a feeble blood sugar lowering effect in this animal—combined to produce a pronounced fall

in blood sugar. These results indicate that the inactivated hormone combined with the animal's antibody, leaving the active insulin free to lower the blood sugar.

DISCUSSION

The experimental production of a species-specific resistance to insulin in the rabbit on an immunological basis is evidence for the antigenicity of insulin and gives further support to the view that some instances of resistance to insulin in man have an immune basis. The element of species specificity explains the coexistence of resistance to exogenous insulin on the one hand and undisturbed utilization of endogenous insulin on the other. This appears to be the case in the resistant rabbit reported herein as well as in certain instances of insulin resistance which have been observed among non-diabetic patients receiving insulin-shock therapy.

It is difficult on the basis of our observations to arrive at a conclusion regarding the antigenic-

ity of insulin in the adjuvant mixture used, owing to the high mortality of our animals. It can be safely stated, however, that with the method used only a small proportion of animals will develop resistance within three months of the time immunization is begun. The possibility remains, however, that all animals might become resistant if immunization were sufficiently prolonged. The failure of other workers to produce unequivocal resistance to insulin on an immunological basis in experimental animals may have been due to the omission of adjuvants and perhaps the use of an insufficiently sensitive test for the detection of resistance. In their paper describing the successful production of complement-fixing antibodies to insulin in rabbits receiving large intravenous and subcutaneous injections of insulin, Wasserman *et al.* state (10) that no resistance to insulin developed. However, the method used in attempting to show resistance was not described. The relationship between complement-fixing antibodies, precipitins and susceptibility to anaphylaxis on the one hand and resistance to insulin on the other will require further investigation.

Earlier studies in this laboratory (1, 2) as well as those reported herein are in conflict with the claim made by Wasserman and Mirsky (11) that insulins from various animal sources are immunologically identical. Indeed the observations in our insulin-resistant animal can hardly be explained other than by assuming different immunologic specificities for rabbit and human insulins on the one hand and beef and pork on the other. There is one possible, but unlikely, explanation for the results obtained by us, which retains the concept of the immunologic identity of all insulins. The assumption can be made that the modern method for the commercial extraction and purification of insulin alters the molecule so as to confer upon it a new immunologic specificity. According to this hypothesis, the resistant animal's antibody is directed against insulin modified by the method currently used in the preparation of commercial insulin and would fail to combine with native insulin (endogenous rabbit insulin) or human insulin extracted by the older method used by us.

The experiment with cysteine-inactivated insulin suggests that the antigenic specificity of the insulin molecule is little altered by inactivation,

a result which is in accord with conclusions reached by Wasserman *et al.* (10). This experiment also indicates that the total available antibody in the resistant animal was not in excess of an amount which would neutralize 60 u of insulin (15 u/kg.). The estimated degree of resistance in this animal may therefore be less than that seen in some instances of human resistance to insulin which may require more than 5000 u in 24 hours (70 u/kg.). However, regeneration of antibody during the 24-hour period may be one factor contributing to the large insulin requirement in such cases.

SUMMARY

Resistance to the hypoglycemic action of commercial crystalline (beef and pork) insulin was induced in the rabbit by the repeated subcutaneous injection of crystalline insulin incorporated in an adjuvant mixture. The resistance to insulin was species-specific, as indicated by both the animal's failure to develop hyperglycemia and the response to human insulin, and appeared to be due to the development of an antibody for insulin. Evidence is presented which indicates that insulin treated with cysteine so as to destroy its hypoglycemic activity retains its capacity to combine with antibody.

We take pleasure in expressing our indebtedness to Miss Jean Buckley for technical assistance.

RELATIVE MEASUREMENT *IN VIVO* OF ACCUMULATION OF RADIOIODINE BY THE HUMAN THYROID GLAND: COMPARISON WITH RADIOACTIVITY IN PERIPHERAL TISSUES¹

By THOMAS J. LUELLEN,² F. RAYMOND KEATING, JR., MARVIN M. D. WILLIAMS, JOSEPH BERKSON, MARSCHELLE H. POWER, AND WILLIAM M. McCONAHEY²

(From the Divisions of Biochemistry, Biometry and Medical Statistics, Biophysics, and Medicine, Mayo Clinic and Mayo Foundation, Rochester, Minnesota)

(Received for publication July 29, 1948)

The gamma rays produced by radioiodine permit its direct measurement *in vivo*, and particularly in the thyroid gland, both of the human subject and of animals, with little or no disturbance of existing equilibria, provided, that is, that the possibility of a biologic effect of radioiodine due to its radiation per se is disregarded. Full realization of the possibilities of this quantitative method of measurement has been thwarted by difficulties of interpreting the observations as well as by numerous technical difficulties which interfere with accuracy in the absolute measurement of radioiodine *in vivo*. These difficulties include geometric problems arising from anatomic variations in the thyroid and surrounding structures and the problem of evaluating the degree of absorption and scattering of radiation that occurs. However, in spite of the foregoing considerations, relative measurements over the thyroid, expressed simply in counts per second, have yielded useful data.

Hamilton and Soley (1) studied the collection of I^{131} by the thyroid in 17 subjects after administration of the radioiodine with 14 mg. of inert iodide as carrier. Data from normal individuals were recorded in smooth curves which reached a plateau about two days after administration of the dose and thereafter remained flat. Curves of collection for patients with nontoxic goiters resembled those of normal persons but larger quantities of radioiodine were collected. Thyrotoxic glands had a maximal uptake of I^{131} in one to four hours and the uptake then fell rapidly in 24 hours to one half to one fifth the maximal value.

A nontoxic goiter in a child who had hypothyroidism showed a curve like that produced by the thyrotoxic glands and the thyroid glands of four children having hypothyroidism without goiter collected only a small amount of radioiodine. Later Hamilton (2) reported that, when 0.1 μ g. instead of 14 mg. of iodide was used as carrier, the maximal uptake in hyperthyroid glands was several times greater and the rapid loss of radioiodine from the thyroid previously observed did not occur. In 1943, Hamilton and his associates (3) reported that the thyroids of two children who had hypothyroidism and goiters collected and retained relatively large amounts of radioiodine. Hertz (4) in 1941 made *in vivo* measurements over the thyroid region and found that the uptake of radioiodine in untreated hyperplastic thyroid glands approached 100 per cent.

Quimby and McCune (5) in 1947 made *in vivo* measurements of radioiodine in children. The mean collection by normal subjects was 12 per cent of the dose. The thyroids of hyperthyroid patients collected substantially more than this whereas hypofunctioning glands collected less than 1 per cent of the dose. Stanley and Astwood (6) in 1947 administered I^{131} in doses of 100 microcuries without carriers to normal subjects for the purpose of assaying antithyroid compounds. When the counts per second recorded over the thyroid were plotted against the square root of time, the observations could be fitted to a straight line, from which was calculated an arbitrary numerical value which they called an "accumulation gradient." The value of this gradient in euthyroid subjects varied from 1.4 to 36.4 with a mean value of 9.4.

Keating, Power, Berkson and Haines (7) have described studies on the excretion of radioiodine in the urine of human subjects. They indicated

¹ Abridgment of thesis submitted by Dr. Luellen to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science in Medicine.

² Fellow in Medicine, Mayo Foundation.

that neither the proportion of a dose of radioiodine eventually excreted in the urine (the renal fraction) nor the rate constant estimated from the curve of urinary excretion could be regarded as direct or quantitative measures of the function of the kidney with regard to excretion of iodine. The former they felt to be a relative quantity depending on the capacity of the thyroid and of other tissues to dispose of iodine as well as of the kidney to excrete it, and the latter they inferred to be the rate of disappearance of radioiodine from blood. McConahey and co-workers (8) confirmed the latter assumption by showing that no significant difference existed between the rate of disappearance of radioiodine from blood, as determined directly by examination of the blood itself, and the rate of disappearance obtained from simultaneous observations on urine. The measure of renal excretion of radioiodine was shown to be the product of the renal fraction and the rate of disappearance of radioiodine from blood.

Keating and associates inferred from their analysis of urinary excretion that the same considerations would apply to the accumulation of

radioiodine by the thyroid; namely, that both the proportion of a dose of radioiodine eventually collected by the thyroid, and the rate constant derived from a curve of radioiodine accumulation by the thyroid, would prove to be *indirect* and *relative* rather than *direct* and *quantitative* measures of the function of the thyroid with respect to accumulation of iodine.

It was the purpose of our investigation to apply the foregoing considerations directly to *in vivo* measurement of radioiodine in the thyroid of human beings and, particularly, to compare the kinetic behavior of radioiodine in the thyroid itself with observations *in vivo* on peripheral tissues, the concentration of radioiodine in the blood and the urinary excretion of this substance.

METHODS AND MATERIALS

The Geiger counter tubes³ used contained mica windows of approximately 3 mg. per square centimeter or about 0.01 mm. thick and 3.0 cm. in diameter. Counts were recorded by means of a scaling circuit with a scale of 256. The principle of a shield as described by Seidlin *et al.* (9) was used; this consisted of a solid lead cylinder 5.2 cm. thick and 11.5 cm. in diameter to interpose be-

³ Manufactured by the Radiation Counter Laboratories.

FIG. 1. APPARATUS FOR *IN VIVO* MEASUREMENT OF RADIOIODINE IN THE THYROID WITH A GEIGER COUNTER

Note shielded counter tube mounted on a roentgen-ray tube standard, movable shield to be interposed between the thyroid and the window of the counter, scaling circuit and recording clock.

FIG. 2. RADIOIODINE ACCUMULATION CURVES IN A CASE OF ADENOMATOUS GOITER WITHOUT HYPERTHYROIDISM ILLUSTRATING THE MAGNITUDE OF THE CORRECTION FOR RADIATION FROM THE BODY AND FROM THE TISSUES OF THE NECK

tween the thyroid gland and the counting tube, which when in place blocked out more than 99.5 per cent of the direct gamma rays from the thyroid gland. To allow enough room to interpose the lead shield and to have the tube far enough away to receive rays from the entire gland a standard distance of 10 cm. above the thyroid and thigh was chosen at which to place the counter tube. Readings taken with the shield were subtracted from readings without the shield. This corrected for background radiation from the entire body.

The counter tube was kept in an assembly attached to a standard so that it could be raised, lowered or turned in any direction (Figure 1). The assembly consisted of a lead cylinder with a wall 16 mm. in thickness surrounding the counting tube. Over the window of the tube at the lower end of the assembly was a 2.7 mm. brass filter. (Low counts were increased by using instead a filter consisting of 0.2 mm. copper with 0.04 mm. lead.) A pad was placed under the patient's neck so that the arch of the neck would remain constant. Adhesive tape was placed over the center of the thyroid. The tube assembly was centered over a cross on the center of the adhesive tape by using a thin brass plate, which exactly fitted the lower end of the tube assembly, and the center of which had a small chain attached to it to act as a plumb line. Readings were taken with and without the shield interposed above the thyroid and then with and without the shield above the thigh and 10 cm. cephalad to the patella. Whenever there was considerable discrepancy between any two readings, a third or fourth reading was made. The measurements over the thigh were made primarily to correct for the radiation due to radioiodine in the extracellular fluids of the neck. Including the time for setting the tube, the time for one

such series as just described which led to a single point on a graph required about 30 minutes.

The I^{131} was given to fasting subjects in 100 μ g. of sodium iodide as carrier. Tracer doses of I^{131} consisted of about 100 to 1,700 microcuries and therapeutic doses of more than 2,500 microcuries. The neck was palpated and the center of the thyroid gland (if palpable) was marked with adhesive tape on which a cross was marked. With the patient lying face upward on a cot, readings were taken with the counter tube set 10 cm. above the thyroid. Readings were made every 30 to 90 minutes for eight hours and daily thereafter.

In a series of seven patients who apparently did not concentrate radioiodine in their thyroid glands, it was found that the average ratio of radioactivity over the neck, compared to that over the thigh after the ratio became relatively constant, was 2.3 with a range of 2.1 to 2.6. Since in each given case the neck-to-thigh ratio would only be approximate, it was arbitrarily decided to subtract two times the reading obtained from the thigh to correct for the radioiodine in the blood and extracellular fluid in the neck. Figure 2 illustrates the magnitude of the corrections which were made for body radiation and radiation of the extrathyroid part of the neck in an average euthyroid subject. The top curve is that which was obtained when neither of these corrections was made. The second curve from the top shows the effect of correction for body radiation (subtraction of the readings over the thyroid area with the shield interposed). The third curve from the top is the one which was used routinely and was obtained by subtracting twice the values for thigh from the values plotted in the second curve from the top. In cases in which the uptake of radioiodine in the thyroid gland was larger, such cor-

FIG. 3. INDIVIDUAL CURVES OF ACCUMULATION OF IODINE IN THE THYROID

a. For normal volunteers and euthyroid individuals with carcinoma of the thyroid. b. For individuals with adenomatous goiters without hyperthyroidism. Some of these appear to collect substantially more than other euthyroid patients. c. For individuals with hyperthyroidism who received tracer doses. Curves constructed from therapeutic doses did not differ significantly.

rections made even less difference than in the case illustrated.

For a patient receiving a large dose of I^{131} for therapeutic purposes, the counting tube was not able to record all the counts. It was necessary in such situations to use a lead filter in addition to the brass filter over the window of the tube. The sensitivity of the tube was checked against a radium standard. Corrections were made for the resolving time of the counting tube, the decay of the I^{131} , and for the various filters used.

Fourteen studies were made of 13 euthyroid subjects including two normal volunteers, three patients having carcinoma of the thyroid of low grade of malignancy and eight patients having adenomatous goiters without hyperthyroidism. Observations in one case were previously reported by Keating and his co-workers. Fifteen studies were made on ten patients who had hyperthyroidism. Six studies were made on six myxedematous patients. Studies of the blood and urine were carried out as described in previous papers (7, 8).

RESULTS

Figure 3a shows individual iodine-accumulation curves of normal volunteers, and of euthyroid patients with thyroid carcinoma of low grade of malignancy; Figure 3b shows the individual curves of euthyroid patients with adenomatous goiters, and Figure 3c the individual curves of patients with exophthalmic goiters receiving tracer doses. Curves obtained in five additional cases of exophthalmic goiter after therapeutic doses and

curves obtained in six cases of myxedema are not shown individually but are summarized in Figure 4. In order to place all subjects on a comparable basis as far as dosage was concerned, observations of radioactivity were expressed as counts per second per millicurie of dosage. That is, the counts per second as observed were divided by the millicuries of dosage before plotting. When different filters were used, a similar adjustment was made for the effect of the filter. Each count observed at 10 cm. was equal approximately to 2.5 microcuries. Such adjustments for dosage and filter are valid as far as they go but comparison from case to case even with these corrections is at best a rough approximation since it takes no account of the varying shapes of the thyroid and the varying locations in the necks in different individuals.

The curves were all exponential. The curves of the normal individuals and of euthyroid patients with carcinomas or adenomas without hyperthyroidism reached their peak value in about 24 to 48 hours and, thereafter, diminished very slowly. The curves of hyperthyroid patients, whether obtained after tracer or therapeutic doses, rose more steeply and to higher peaks and, thereafter, decreased more rapidly than the curves of euthyroid persons. It made no apparent differ-

FIG. 4. COMPOSITE ACCUMULATION CURVES CONSTRUCTED FROM THE MEAN OBSERVATIONS FOR EACH POINT IN TIME FOR EACH GROUP

The curve for myxedema represents six cases, in none of which did the thyroids retain significant quantities of radioiodine. The curve for therapeutic doses in hyperthyroidism does not differ significantly from the curve for tracer doses.

FIG. 5. COMPOSITE CURVES OF RADIOACTIVITY OVER THE THIGH CONSTRUCTED FROM THE MEAN OBSERVATIONS FOR EACH POINT IN TIME FOR EACH GROUP

These curves correspond in form to those obtained by McConahey and associates by analysis of blood samples.

ence in the shape of the curves or in their apparent magnitude expressed as counts per second per millicurie whether tracer or therapeutic doses were measured. There was some overlapping between the lowest curves for hyperthyroid patients and the highest curves for euthyroid subjects. The curves obtained in cases of myxedema showed little or no accumulation of radioiodine in the thyroid.

Figure 4 shows the composite curves for each of the four types of condition studied computed from the means of the observations versus time: (1) euthyroidism, all cases, (2) hyperthyroidism with tracer doses, (3) hyperthyroidism with therapeutic doses, and (4) myxedema. The peaks in cases of hyperthyroidism were about three times as great as the peaks in cases of euthyroidism and half of the peak value was reached in less than two hours while the euthyroid curve reached half its peak value in about four hours.

Two patients were studied who clinically were thought to have hyperthyroidism but who failed to collect radioiodine. The neck-to-thigh ratio in each case was approximately 2:1 and in each the radiation over the neck decreased at the same rate as over the thigh. No concentration of radioactivity could be detected in the pelvis or other parts of the body.

One patient was a nervous woman, aged 33 years, whose basal metabolic rates ranged from +23 to +37 per cent. She had taken iodine for a year and had discontinued its use two weeks prior to the tracer study. At operation 6 gm.

representing approximately three fourths of the thyroid was removed. It showed slight parenchymatous hypertrophy. Thyroidectomy did not relieve her symptoms.

The second patient was a woman, aged 38 years, whose basal metabolic rates varied from +18 to +23 per cent. Biopsy of the skin disclosed lupus erythematosus; the spleen was enlarged, and the thyroid was not palpable. A cholecystogram had been made 12 days before radioiodine was given. No improvement followed a therapeutic trial of Lugol's solution. Thyroidectomy was not performed.

In Figure 5 composite curves of observations over the thigh are plotted as counts per second per millicurie of dose against time in hours. The conditions studied were (1) euthyroid state in 11 cases; (2) hyperthyroidism in 11 cases, and (3) myxedema in six cases. The curve for patients who had hyperthyroidism had the lowest peak. This was reached within 30 minutes after observations were begun and values, thereafter, decreased the most rapidly of any of the three groups; that is, it decreased to one half of its peak value in two and a half to three hours. The curve for euthyroid patients reached its peak in one hour, at a higher level, and fell more slowly, reaching its half value in about six hours after the peak was reached. Finally, the curve for myxedematous patients indicated that the peak of radioactivity in the blood and extracellular fluid was not reached until about two to three hours after oral administration of I^{131} . This peak was

the highest of the three, and half of the peak value was reached in about 11 to 13 hours. The counts from the thigh with small tracer doses were small and inaccurate owing to the low level of radioactivity. The similarity between curves of measurements from the thigh and from the blood was most striking.

COMMENT

Observations with a Geiger counter, and in particular observations *in vivo*, are subject to numerous sources of error. These include variations in the sensitivity and stability of the counter tube, a statistical counting error which varies with the counting rate as compared to the background count and in the case of high counts a systematic error resulting from the resolving time of the tube. Such purely physical errors can be corrected or minimized by careful technic, but despite the utmost care such errors place a definite limit on the precision of *in vivo* counting. Other errors arise from a consideration of the varying size and shape of the thyroid and surrounding structures in different individuals, variations in radiation entering the apparatus from other parts

of the body than that being measured and so forth. To a certain extent these too can be minimized but not eliminated by careful technic. It is impossible to express quantitatively the net error in the observations which result from the sum of the foregoing and the efforts to minimize them. Such errors become especially important when an attempt is made to measure radioactivity in some absolute term, but even in the present case, in which radioactivity is measured in counts per second, at various intervals of time, one must regard the observations as having an error of the order of magnitude of perhaps 10 per cent. Minor fluctuations, therefore, might easily occur in the quantity of radioiodine in the thyroid which could not be detected by this method.

Inspection of the curves in Figure 3 indicate that, as shown by other observers, the hyperplastic thyroids of hyperthyroid patients accumulate much larger quantities of radioiodine and do so more rapidly than do the thyroids of euthyroid individuals. It is unfortunate that a larger group of normal persons were not available for comparison. We have been reluctant to perform radioiodine studies on more normal volunteers at the

FIG. 6. CURVES DENOTING ACCUMULATION OF RADIOIODINE IN A CASE OF ADENOMATOUS GOITER WITHOUT HYPERTHYROIDISM

Curves were constructed from simultaneous observations made over the thyroid and the thigh and analyses for radioiodine in samples of blood and urine. Note that thyroid and urine curves are similar in form and that blood and thigh curves resemble each other closely. That all four have a common denominator is indicated by the fact that all tend to level off at about the same time.

doses which present technics require because of a growing concern over the quantity of radiation involved. This may be of the order of 12 roentgens equivalent physical (r.e.p.) per day initially and a total integrated dose of the order of 150 r.e.p. when 100 microcuries of I^{131} are given. So far as our observations show, the thyroids of euthyroid individuals with thyroid malignancy of low grade behave in an essentially normal fashion, as do most thyroids of euthyroid individuals with small or moderate adenomatous goiters without hyperthyroidism. For purposes of comparison with hyperthyroid and hypothyroid patients these have been included. In the cases of malignant disease of the thyroid included in this study the malignant tissue, so far as could be determined, did not collect a measurable amount of radioiodine. In a large group of cases of adenomatous goiter without hyperthyroidism in which the urinary excretion of radioiodine was studied, considerably more variation in the behavior of the radioiodine occurred than in other euthyroid groups. A certain proportion of the thyroid glands of these patients, particularly the large nodular goiters, behaved more like hyperthyroid than euthyroid glands. The radioiodine-accumulation curves of the adenomatous goiters without hyperthyroidism included in the present study (Figure 3b) in general resembled those of normal subjects and euthyroid patients with malignant lesions, although several patients retained larger quantities of iodine in their thyroids. One patient in particular (Case 8, Figure 3b) collected more iodine and did so more rapidly than any other euthyroid individual studied. It is probable, therefore, that adenomatous goiters, especially large ones, ought not to be regarded as entirely normal in function even in the absence of clinical hyperthyroidism.

The form of the curve of accumulation of iodine in the thyroid appears on inspection to be exponential and resembles closely the curves constructed from observations of urinary excretion in a previous paper. Furthermore, the form of the curve of radioactivity over the thigh corresponds closely to that constructed from determinations of radioiodine in blood serum. Figure 6 illustrates the relationships of all four types of observations in a case of adenomatous goiter without hyperthyroidism. The existence of a rate constant

common to all four curves can be inferred from the fact that they all tend to level off at about the same time. It is of interest, therefore, to analyze these curves in the manner employed by Keating, Power, Berkson and Haines (7) for the study of urinary excretion of radioiodine.

ANALYSIS OF CURVES

Observations of the quantity of radioiodine in the thyroid can be fitted with an exponential function of the form

$$Q_{\text{thyroid}} = Q_t = Q_{\infty} (1 - e^{-rt})$$

where Q_t is the quantity of radioactivity expressed as counts per second in the thyroid at any time, Q_{∞} the asymptotic (*time* = infinity) value of the function Q_t , and r a rate constant. Similarly the descending portion of the observations made over the thigh can be fitted with an exponential function of the form

$$Q_{\text{thigh}} = Q_s = Q_{s0} (e^{-rt})$$

where Q_s is the quantity of radioactivity in counts per second at time t and Q_{s0} is the value of the function corresponding to $t=0$. The parameters Q_{∞} and r for the thyroid curve were evaluated by the method previously described, consisting of plotting $\log (Q_{\infty} - Q_t)$ against t for various estimated values of Q_{∞} until the relationship fits a straight line, and from the slope of this line evaluating r . In the case of the curve for the observations of the thigh, the parameters Q_{s0} and r are evaluated from a straight line fitted to the plot of $\log Q_s$ against t .

Table I shows the values for the rate constant r as evaluated in the same patients from (1) the curves of accumulation of radioiodine in the thy-

TABLE I
Values for the rate constant r determined from urine, thyroid and thigh

Condition	Cases	r (per cent per hour), mean*			Variability of r †	
		Urine	Thyroid	Thigh	(S.D.) ² variance	P
Euthyroid	14	13.8 ± 0.9	13.5 ± 0.9	14.4 ± 1.0	3.18	>0.05
Hyperthyroid	15	37.9 ± 3.3	40.3 ± 3.7	36.2 ± 3.1	26.73	>0.05
Hypothyroid	6	5.93 ± 0.3	6.10 ± 0.5	6.65 ± 0.6	0.70	>0.05

* The value after the \pm is the standard error of the mean.

† The variability of r for each case was calculated as the variance (squared S.D.) of the three estimates derived (urine, thigh, thyroid); the value in the table is the mean variance for the group. The P value was calculated by the method of analysis of variance (10) to determine whether the differences among the determined r 's were significant statistically. A value of $P < 0.05$ is generally considered a good criterion of significance. (For none of the groups was it indicative that the r 's determined in the different ways were different.)

TABLE II

Values for rate constant r determined from urine, blood, thyroid and thigh

Condition	Cases	r (per cent per hour), mean*				Variability of r †	
		Urino	Blood	Thyroid	Thigh	(S.D.) ² variance	P
Euthyroid	6	14.5±1.1	15.0±0.8	12.9±1.1	14.0±1.0	3.76	>0.05
Hyperthyroid	7	39.0±5.3	39.3±5.5	40.6±6.6	37.0±5.1	26.84	>0.05
Hypothyroid	4	6.0±0.5	8.5±1.3	6.0±0.7	6.9±0.5	2.68	>0.05

* The value after the \pm is the standard error of the mean.

† The variability of r for each case was calculated as the variance (squared S.D.) of the four estimates derived (urine, blood, thigh, thyroid); the value in the table is the mean variance for the group. The P value was calculated by the method of analysis of variance (10) to determine whether the differences among the determined r 's were significant statistically. A value of $P < 0.05$ is generally considered a good criterion of significance.

roid, (2) observations over the thigh, and (3) analysis of urinary excretion. Table II shows a similar comparison in those cases included in the first table in which, in addition to the foregoing, the concentration of radioiodine in blood also was determined. It appears from the analysis in both tables that the rates obtained by these various methods are not significantly different from one another either in the individual cases or when the means for the various groups are compared. The actual values obtained in an individual case do show some random variation from one method to another which can be ascribed to the errors in the analytical methods employed and in addition to inaccuracies arising from the methods of curve fitting employed for the estimation of the rates. The rate as determined from analysis of the thyroid curve is the same as that obtained from observations over the thigh, on the urine and on the blood. It is not a measure of thyroidal accumulation rate, but like the rate constant derived from urine represents the proportional rate of disappearance of radioiodine from blood. This follows from the same analysis on which the previous calculations of Keating and associates were based. The rate of disappearance of radioiodine from blood, however estimated, usually varies according to the state of thyroidal activity. No matter how measured it is not a quantitative or direct measure of accumulation of iodine in the thyroid gland, since it must measure the rate

at which iodine disappears from the blood into all sites of disposal including the urine and other tissues as well as the thyroid.

SUMMARY

A method is described for making relative *in vivo* measurements of the quantity of radioiodine accumulated by the thyroid. Accumulation of radioiodine by the thyroid has been measured in 29 individuals having various states of thyroidal function. These measurements have been compared with observations over the extremities (thighs), with measurements of urinary excretion and with analysis of blood for radioiodine.

In vivo observations over the thyroid show substantially more radioiodine accumulated by the thyroids of hyperthyroid individuals than by the thyroids of euthyroid individuals. Euthyroid patients with nodular goiters may at times collect more radioiodine in their thyroids than other euthyroid subjects. Hypothyroid patients show little or no accumulation of iodine in their thyroids.

The accumulation of radioiodine by the thyroid was observed to follow an exponential curve similar in form to the curve of urinary excretion of radioiodine. Observations of radioactivity over the thigh, on the other hand, resembled closely curves constructed from analyses of radioiodine in serum.

Estimation of the exponential rate constant of the curve of radioiodine accumulation by the thyroid was found to have the same value as the rate constant estimated from observations over the thigh, from observations of urinary excretion or from analyses of blood for radioiodine. This rate is regarded as representing the rate of disappearance of radioiodine from blood no matter which method is used to obtain it.

The rate of disappearance of radioiodine from blood varies according to the state of thyroidal activity. Even when obtained directly from observations on the thyroid *in vivo*, however, it does not provide a direct or quantitative measure of the accumulation of radioiodine by the thyroid, since it must measure the rate of disappearance of radioiodine from the blood into all sites of disposal, including the urine and other tissues as well as the thyroid.

THE MEASUREMENT OF THE IODINE-ACCUMULATING FUNCTION OF THE HUMAN THYROID GLAND

By F. RAYMOND KEATING, JR., J. C. WANG,¹ THOMAS J. LUELLEN,²
MARVIN M. D. WILLIAMS, MARSCHELLE H. POWER,
AND WILLIAM M. McCONAHEY²

(From the Divisions of Biochemistry, Medicine, and Physics and Biophysical Research,
Mayo Clinic and Mayo Foundation, Rochester, Minn.)

(Received for publication July 30, 1948)

At least two distinct mechanisms appear to be responsible for accumulation of iodine by the thyroid gland. The first, called the "iodide trap" by Vanderlaan and Vanderlaan (1), involves the concentration, presumably within the thyroid cells, of inorganic iodide obtained from the circulating blood. The second, called hormonal synthesis, involves the utilization of the trapped iodide for the synthesis of organic iodine compounds (chiefly diiodotyrosine and thyroxine) which are then stored in the colloid in thyroglobulin.

Vanderlaan and Vanderlaan (1), and Taurog, Chaikoff and Feller (2) have shown in the rat that, even after hormonal synthesis has been blocked by an antithyroid drug such as propylthiouracil, the thyroid concentrates relatively large quantities of radioiodine. The radioiodine so concentrated remains in the form of iodide and Taurog and associates have shown that it leaves the thyroid at a rate which parallels the decrease of radioiodine in the blood, suggesting that an equilibrium exists between the two. This ability to concentrate radioiodine can be promptly abolished by the administration of thiocyanate, which thus appears to act as a specific poison to the iodide trap.

The iodide-concentrating function has been studied in the human thyroid by Stanley and Astwood (3), who gave tracer doses of I^{131} some hours after administration of a dose of mercaptoimidazol or propylthiouracil. Significant concentration of radioiodine occurred in the thyroid, reaching a peak in one to three hours, thereafter decreasing and largely disappearing within 24 hours. Administration of potassium thiocyanate after the curve of iodine concentration in the thyroid had reached a maximum was followed

by abrupt disappearance of the radioiodine from the thyroid within an hour.

The foregoing is in marked contrast to the manner of accumulation of radioiodine by the untreated thyroid gland (4, 5). The accumulation of radioiodine in the unblocked thyroid can be expressed by an exponential curve which levels off between 24 and 48 hours and thereafter the quantity present in the thyroid diminishes gradually over a period of several weeks. Hyperfunctioning glands accumulate radioiodine both more rapidly and in larger quantities than normal glands and subsequently lose the radioiodine more rapidly than normal glands. Analyses of thyroid tissue removed 48 or more hours after administration of a dose of radioiodine reveal that more than 90 per cent of the radioiodine present is organically combined (6). Taurog and Chaikoff (7) have shown that the untreated thyroid gland of the rat converts the radioiodine which it accumulates to organic form with astonishing rapidity, 95 per cent of the quantity present in the thyroid being organically bound as early as 15 minutes after the dose has been given. The accumulation curve of the untreated thyroid gland may thus be regarded as reflecting both the iodide-trapping and the synthetic function, but it seems probable that both the maximal point in the curve and the rate at which accumulation occurs reflect hormonal synthesis more than trapping.

The accumulation of iodine by the human thyroid as disclosed by radioiodine has been shown to vary significantly in varying states of thyroid activity (4, 8, 9) and has attracted attention both as an aid in diagnosis of thyroid disease and more importantly as a new approach to the clinical study of normal and disordered thyroid function. It represents a distinctly different aspect of thy-

¹ Fellow in Biophysics, Mayo Foundation.

² Fellow in Medicine, Mayo Foundation.

roid function than other measures of thyroidal activity ordinarily employed clinically, such as protein-bound iodine, basal metabolic rate and blood cholesterol.

In vivo measurement of the quantity of radioiodine in the thyroid involves a number of technical difficulties. In order to convert the counts recorded by a suitable Geiger counter to absolute terms such as microcuries or percentage of the dose given, *in vivo* measurements must be compared with suitable standards. Account must be taken of the stability and efficiency of the counting tube employed, the geometric relation of the apparatus to the subject, the depth and dimensions of the thyroid, the radioactivity in other parts of the body and such factors as absorption and scattering of photons by the thyroid and the tissues which surround it. *In vivo* measurement is thus subject to observational errors of considerable magnitude.

A number of investigators have dealt with these problems. In 1940 Hamilton and Soley (4) made the first attempt to determine the absolute amount of I^{131} collected in the thyroid. Their method consisted in measuring the radioactivity over the anterior and posterior (seventh cervical vertebra) aspects of the neck. The ratio of these values represented the proportion of radiation from the thyroid which penetrated to the back of the neck. The "correct" value for the radioactivity in the thyroid was calculated from this by comparison with a suitable standard of radioiodine. In 1946 Seidlin, Marinelli and Oshry (10) shielded their Geiger counter with 1.91 cm. of lead and measured the radioactivity through a window in the lead shield. The difference between the reading with the window open and that with the window plugged with a 1.91 cm. thickness of lead represents the radioactivity of the region being measured. The absolute value was then determined by comparing this reading with that of a known amount of I^{131} . In 1947 Uimby and McCune (11) made absolute measurements by placing their Geiger counter directly over the neck and comparing these readings with those of known samples in a "phantom."

The iodine-accumulating function of the thyroid has been estimated from *in vivo* observations in various ways: 1) by measuring the quantity of radioiodine maximally accumulated (4, 8, 9);

2) by measuring the quantity accumulated in some selected period (10, 11); 3) by observing the relative form and magnitude of the iodine-accumulation curve (4, 5); 4) by estimating from this curve an arbitrary accumulation gradient (12); or 5) by determining the rate constant of the exponential accumulation curve (5). Since Hamilton and Soley had shown that most of a dose of radioiodine was either collected by the thyroid or excreted in the urine, some observers (13) have employed measurements of the quantity excreted in the urine in a selected period, usually 48 hours, to estimate the proportion of the dose collected by the thyroid. There appears to be need for data regarding the relationships of such diverse observations to one another and their individual validity as quantitative measures of iodine-accumulating function.

Keating, Power, Berkson and Haines (14) estimated from the curve of urinary excretion of radioiodine two values: (a) the asymptotic quantity in the urine, which they termed the "renal fraction"; (b) a rate constant, which they considered to represent the disappearance rate of radioiodine from blood. The product of these values, which they called "renal excretion rate," they regarded as the most direct measure of renal function with regard to iodide excretion. The difference between excretion rate and disappearance rate represented disposal of iodine by all tissues other than the kidneys, and was called "collection rate"; a more exact term would have been "extrarenal disposal rate." In so far as the thyroid is the most important site for the extrarenal disposal of iodide, the latter value should provide an index of the rate of iodine accumulation by the thyroid. In support of the interpretation of Keating and co-workers, McConahey and associates (15) determined the rate of disappearance of radioiodine from blood directly from measurements of samples of plasma and found good agreement with estimates of this value obtained from curves of urinary excretion by the method employed by Keating, Power, Berkson and Haines. Luellen and co-workers (5) observed that the rate constants estimated from curves simultaneously obtained from: 1) *in vivo* observation of radioiodine in the thyroid in counts per second; 2) measurement of radioactivity in peripheral tissues (the thigh); and 3) urinary

excretion of radioiodine, all appeared to be the same as the rate of disappearance of radioiodine from blood as determined directly. It was suggested therefore that *in vivo* observations of radioiodine in the thyroid might be analyzed in the same manner as the data for urinary excretion of radioiodine. Thus the product of the asymptotic quantity in the thyroid (expressed as a fraction of the dose given) by the disappearance rate of radioiodine from blood gives the quantity iodine-accumulation rate analogous to the quantity renal excretion rate.

It is the purpose of this communication: 1) to describe an empirical method for measuring *in vivo* the quantity of radioiodine in microcuries collected by the human thyroid gland; 2) to present methods for estimating the iodine-accumulation rates from such data; and 3) to compare iodine-accumulation rate with other measures of the iodine-accumulating function of the human thyroid which may be derived from *in vivo* observations and studies of urinary excretion after oral administration of radioiodine.

METHODS

Radioiodine emits both beta and gamma radiation. The beta radiation will not penetrate much more than 2 or 3 mm. of tissue before being totally absorbed, whereas a large proportion of the gamma radiation will penetrate the tissue and continue in air for several meters. Since the gamma radiation will be emitted uniformly in all directions, its intensity at any distance from the gland should be inversely proportional to the square of the distance, provided one assumes the thyroid to be small enough to be considered a point source. Hence, by placing the Geiger counter at two different distances, P and Q , from the neck one should obtain two intensities, I_p and I_q , which would be inversely proportional to the squares of the distances, A and B , from the focus of radiation to the effective portion of the counter. However, the measurable distances, P and Q , are only from the surface of the skin to the outer surface of the counter. There remains a nonmeasurable portion, x , which represents the depth of the thyroid from the surface of the skin plus the depth of the effective portion of the counter from its surface. It is obvious then that:

$$A = P + x, \quad 1$$

$$B = Q + x, \quad 2$$

where A and B are the true distances. The relation of these quantities to each other is given by the equation

$$\frac{A^2}{B^2} = \frac{(P+x)^2}{(Q+x)^2} = \frac{I_q}{I_p} \quad 3$$

and x , and hence A and B can be calculated from it when P , Q , I_p , and I_q have been measured.

To quantitate the measurements in millicuries or microcuries, the foregoing procedure is first used with a known standard of I^{131} . The Geiger counter being thus calibrated, it is possible to compute the amount of I^{131} in the thyroid in millicuries or microcuries. It must be added that the background radiation is measured after each setting with a lead cylinder 5 cm. long and 9 cm. in diameter (which absorbs more than 99 per cent of the radiation going from the thyroid to the counter) interposed between the area that is being measured and the counter. This reading includes the cosmic radiation, radiation from the thyroid which has been scattered into the counter from other parts of the body, and direct radiation from I^{131} located in parts of the body other than the area being measured. The measurements were carried out with the apparatus and general procedure previously described by Luellen and associates (5). An empirical correction was made for radioiodine in the neck and not in the thyroid by subtracting twice the value of radioactivity recorded in the thigh. Except in the case of comparatively small accumulation in the thyroid, the latter correction is relatively insignificant.

To determine the extent to which geometric relations, absorption and backscatter affect the measurements, samples of I^{131} solution of similar activity but of different diameters were embedded in paraffin phantoms (1, 3 and 6 cm. diameter and 0.5 cm. deep). It was found that when distances (P and Q) of 25 and 45 cm. were used the "inverse-square" relationship was valid to within ± 5 per cent. When the I^{131} was not more than 3.5 cm. below the surface, absorption of the radiation by the paraffin above the solution was compensated for by the backscatter from below and lateral to the source. For depths greater than 3.5 cm. the absorption was greater than the backscatter and the apparent amount of radioactivity decreased approximately 4 per cent per centimeter of paraffin. Hence it would appear that this method of determining the amount of I^{131} in the thyroid should give results which are correct to within ± 15 per cent.

Serial *in vivo* observations were made of 30 subjects including 11 patients who had myxedema,³ five euthyroid patients who had low-grade thyroid tumors, seven patients who had adenomatous goiter without hyperthyroidism and seven patients who had exophthalmic goiter. One or more *in vivo* observations were made on 26 addi-

³ The 11 cases of myxedema included in this study were all instances of severe spontaneous or postoperative myxedema in which *in vivo* studies did not show any measurable accumulation of radioiodine in the thyroid region. Certain cases of myxedematous states have been observed in which varying degrees of iodine accumulation, sometimes of surprising extent, were observed in the thyroid. For the most part these included cases of thyroiditis, struma lymphomatosa and cyanate goiter. Such cases have been omitted from this study and will be made the subject of subsequent reports.

tional persons: 11 euthyroid patients who had thyroid tumors, six patients who had adenomatous goiter without hyperthyroidism and nine patients who had exophthalmic goiter. In all instances, the urine was carefully collected and analyzed for radioiodine in the manner described by Keating and associates (14).

As in previous studies, both tracer and therapeutic doses are included in the series, careful comparison of the behavior of tracer versus therapeutic amounts in patients receiving both having failed to disclose consistent or significant differences either in the quantity of iodine initially accumulated by the thyroid or in the kinetic relationships involved during the first day or two after administration of the dose.

In the interest of clarity the various values employed in this paper may be defined as follows: From the curve of urinary excretion of radioiodine are derived (1) the renal fraction (Q_{uf}), defined as the asymptotic ($t = \infty$) quantity of radioiodine excreted in the urine expressed as a fraction of the dose; (2) the disappearance rate (r), defined as the proportional rate at which radioiodine disappears from the blood into all sites of disposal; (3) the renal excretion rate, defined as the proportional rate of excretion of radioiodine by the kidneys (This is obtained by taking the product of the renal fraction and the disappearance rate [$Q_{uf} \times r$]); (4) the extrarenal disposal rate, which in previous publications was called "collection rate," defined as the proportional rate of disappearance of radioiodine into all sites other than the urine. This is obtained by subtracting the renal excretion rate from the disappearance rate ($r [1 - Q_{uf}]$).

From the curve of accumulation of the radioiodine by the thyroid as measured *in vivo* can be obtained (5) the thyroid fraction (Q_{if}) defined as the asymptotic ($t = \infty$) quantity of radioiodine accumulated by the thyroid expressed as a fraction of the dose; (6) the disap-

pearance rate (r) defined as in the previous paragraph; (7) the iodine-accumulation rate, defined as the proportional rate of accumulation of iodine by the thyroid (This is obtained by taking the product of the thyroid fraction and the disappearance rate [$Q_{if} \times r$]); (8) the extra-thyroidal disposal rate, defined as the proportional rate of disappearance of radioiodine into all sites other than the thyroid. This is obtained by subtracting the accumulation rate from the disappearance rate ($r [1 - Q_{if}]$).

The renal fraction and the disappearance rate were estimated from observations on urine as previously described (14). The thyroid fraction and the disappearance rate have been estimated from *in vivo* observations of the thyroid as described by Luellen and his associates (5), except that the quantities in the thyroid have been expressed in actual terms as percentage of dose instead of in relative terms as counts per second.

Reference will also be made to (9) accumulation gradient, a term coined by Stanley and Astwood (12) and defined by them as the slope of a line obtained by plotting thyroid accumulation of radioiodine in counts per second per 100 microcuries of dose against the square root of time. The value is obtained by dividing the increase in counts per second during a given period against the number resulting from subtracting the square root of time in minutes at the beginning of the period from the square root of time in minutes at the end of the period.

RESULTS

In Table I are summarized the means of the various values estimated from the curve of urinary excretion and from the curve of *in vivo* observations obtained simultaneously over the thyroid. For comparison are included (10) the mean quantities of iodine observed in the thyroid 12

TABLE I

‡ The values given are the means and the standard errors of the means.

hours after administration of the dose, and the accumulation gradient as defined by Stanley and Astwood (12).

Of the ten values shown in Table I, eight vary significantly with variations in thyroidal activity and two do not. Renal excretion rate (3) is regarded as a measure of renal function with respect to iodine. Extrathyroidal rate of disposal (8) measures the rate of disposal of iodine by all tissues other than thyroid, including kidneys. As noted elsewhere, the mean disappearance rates (2 and 6) obtained by the two types of observations do not differ significantly.

Attention is called particularly to the magnitude by which the mean values differ in various states of thyroid activity. The renal fraction (1) is twice as high in the euthyroid patients as in the group having exophthalmic goiter but only a fourth higher in myxedema than in the euthyroid patients. The thyroid fraction (5) on the other hand is 3.0 times as great in exophthalmic goiter as in the euthyroid group. It will be noted that the quantity of iodine actually observed in the thyroid after an arbitrarily selected interval (12 hours), also varies by about the same amount, being 3.4 times as great in exophthalmic goiter as in the euthyroid group.

Disappearance rate (2 and 6) is 2.6 times as high in exophthalmic goiter as in the euthyroid group, extrarenal disposal rate (4) is 5.5 times as high in exophthalmic goiter as in the euthyroid group, while the accumulation rate (7) differs by a factor of 8.4 and Stanley and Astwood's accumulation gradient (9) by a factor of 8.1.

It will be noted that the values for the group having adenomatous goiter without hyperthyroidism are to some degree intermediate between euthyroid and hyperthyroid groups. It was observed that large adenomatous goiters tended to show increased avidity for iodine even in the absence of clinical evidences of hyperthyroidism.

The foregoing data were accumulated from serial *in vivo* observations obtained over a period of several days. Such serial observations provide a method of evaluating disappearance rate as described by Luellen and associates (5) and also for assigning a value to the thyroid fraction. Sufficient observation to enable one to construct a reasonably accurate curve is quite time-consuming both to patient and to observer and ties up

the apparatus for the greater part of two days. Even so, there is likely to be an annoying hiatus in the curve unless observations are also made during the night. For these reasons a less time-consuming method for evaluating iodine-accumulation rate might have some advantages.

Since the rate of disappearance of radioiodine from blood can be calculated from measurements over thyroid, peripheral tissues, urine or blood, one should be able to calculate with reasonable accuracy the value of thyroid accumulation rate from (a) a single accurate measurement over the thyroid made during the period of radioiodine accumulation, and (b) the value for disappearance rate calculated from urine as described elsewhere. The thyroid fraction can be approximated from the curve of urinary excretion and a single *in vivo* measurement from the equation $Q_{tf}/Q_{uf} = Q_t/Q_u$ where Q_t is the quantity measured in the thyroid, Q_u the quantity excreted in the urine up to the time of the thyroid measurement, Q_{tf} the thyroid fraction and Q_{uf} the renal fraction. Accumulation rate estimated in this way is probably less accurate than an estimate based on serial observations *in vivo*, for the reason that a value based on a series of such measurements is less dependent on the error of any one observation than is a value based on a single observation.

In Table II are shown mean values for accumulation rate for the same groups of cases in-

TABLE II
Comparison of accumulation rates estimated
by two methods

Group	Cases	Accumulation rate		Means of individual differences
		Estimated from serial <i>in vivo</i> observations over the thyroid	Estimated from urinary curve and one <i>in vivo</i> observation over the thyroid	
		per cent/hour	per cent/hour	per cent/hour
Euthyroid patients who had thyroid tumors	5	$2.4 \pm 0.7^*$	2.6 ± 0.8	$+0.2 \pm 0.2$
Adenomatous goiter without hyperthyroidism	7	4.6 ± 1.3	4.2 ± 0.9	-0.4 ± 0.5
Exophthalmic goiter	7	20.2 ± 5.6	18.0 ± 4.4	-2.2 ± 1.6

* The values given are the means and the standard errors of the means.

TABLE III

Accumulation rates estimated in a second series of patients from urinary excretion and single observations in vivo over the thyroid

Group	Cases	Basal metabolic rate	(1) Renal fraction	(2) Disappearance rate	(4) Extrarenal disposal rate	(7) Accumulation rate

* The values given are the means and the standard errors of the means.

cluded in Table I, comparing estimations based entirely on *in vivo* measurements with estimations in the same cases made in the manner just enumerated. The values obtained with each method agree fairly well with each other.

Table III shows accumulation rates for a second group of cases, estimated from urinary excretion curves and single *in vivo* observations over the thyroid. For comparison the various values obtained from the urine alone are also included. The same relationships noted in the first group (Table I) hold here; namely, that the most striking differences are encountered in the accumulation rate and the extrarenal disposal rate.

If all of the iodine given to the patient either appeared in the urine or was collected by the thyroid, then (a) renal fraction (1) plus thyroid fraction (5) should equal 100 per cent; (b) extrarenal disposal rate (4) should equal accumulation rate (7); and (c) extrathyroidal disposal rate (8) should equal renal excretion rate (3). However, it is found that this is not the case. Renal plus thyroid fractions consistently total less than 100 per cent, extrarenal disposal rates are consistently larger than accumulation rates, and extrathyroidal disposal rates are consistently larger than renal excretion rates. The difference between the sum of renal and thyroid fractions and 100 per cent will provide some measure of the fraction of the dose disposed of elsewhere than in kidneys or thyroid. The rate of disposal by tissues other than kidneys or thyroid can be approximated by extrarenal disposal rate (4) minus accumulation rate (7) or alternatively by extra-

thyroidal disposal rate (8) minus excretion rate (3). The "tissue rate" so estimated by either method for any case would have the same value providing the estimate of disappearance rate obtained from thyroid is identical with that obtained from urine, a circumstance which is unlikely owing to the errors in the observations.

In Table IV are given the means of the foregoing values for those cases in which serial observations over the thyroid were made. It is of interest that the fraction of the dose unaccounted for is about the same (12.5 per cent to 13.6 per cent) in all four groups of cases and that the mean rate of extrarenal disposal for the group having myxedema is of about the same order of magnitude as the estimates of "tissue rates" for the other groups. These values would represent any radioiodine excreted in feces, sweat or expired air as well as any radioiodine fixed in tissues such as muscle or liver. These values will also, unfortunately, bring into prominence any loss of iodine in the collection of urine, any error resulting from the methods of measurement employed and any error inherent in the methods by which the various values were derived. Estimates of disposal of iodine by tissues other than kidneys and thyroid vary considerably from case to case, and for the reasons given they must be regarded as relatively inaccurate and probably too high. On this account it is not apparent from this small

TABLE IV

Disposal of iodine by tissues other than kidneys and thyroid

Group	Cases	Fraction of dose unaccounted for	Extrarenal disposal rate (4)-accumulation rate (7)	Extrathyroidal disposal rate (8)-renal excretion rate (3)
		per cent of dose	per cent/hour	per cent/hour
Myxedema*	11	13.6±2.0†	0.9±0.3	
Euthyroid patients who had thyroid tumors	5	13.1±2.9	1.5±0.4	2.3±1.1
Adenomatous goiter without hyperthyroidism	7	13.2±3.5	1.6±0.8	1.9±1.2
Exophthalmic goiter	7	12.5±4.3	1.4±1.1	5.9±2.1

* In the group having myxedema the values given are (a) 100 per cent—renal fraction and (b) extrarenal disposal rate alone, there being no thyroidal accumulation.

† The values given are the means and the standard errors of the means.

series whether any significance should be attached to the relatively greater value for tissue rates in cases of exophthalmic goiter.

COMMENT

Previous studies have dealt with various aspects of the kinetic behavior of radioiodine, on the basis of observations of urinary excretion of radioiodine (14), the concentration of radioiodine in the blood (15) and the quantity of radioiodine in the thyroid or peripheral tissues as measured *in vivo* in counts per second (5). The present study adds to these some *in vivo* observations which are expressed in absolute terms. The results enumerated permit a comparison of various measures in a search for the most appropriate and precise method of evaluating quantitatively the capacity of the thyroid to accumulate iodide by means of observations made with radioiodide. An ideal measure of this function of the thyroid should be expressed in terms which are independent of the dose of radioiodine given and should reflect the accumulation of iodide by the thyroid alone, uninfluenced by irrelevant changes which might occur in the kidneys or in other tissues, or in water exchange.

Measurement of the quantity of radioiodine in thyroid or urine. Direct measurement *in vivo* of the quantity of radioiodine in the thyroid after some interval of time might at first glance appear the most appropriate measure of iodine-accumulating function. This is not true for the reason that the thyroid must in effect compete with the kidneys and other tissues for the limited quantity of iodine provided in the tracer dose. The quantity of radioiodine accumulated by the thyroid in any given period, as well as the quantity eventually or asymptotically accumulated, is a relative quantity, depending on the function of the kidneys and other tissues as well as on the iodine-accumulating function of the thyroid itself. On this basis even if the thyroid function with respect to iodine accumulation remains quite constant, a variation in function of the kidneys or perhaps of other iodine-collecting tissue should alter the picture of iodine accumulation by the thyroid. Thus, if the ability of the kidneys to excrete iodine was decreased, the amount of iodine accumulated in any given time by the thyroid should increase and so should the total amount eventually accu-

mulated. These relationships may be important even if pathologic alteration of the function of the kidneys or other tissues with respect to iodine is not involved. In euthyroid persons, the kidneys and other tissues account for the disposal of three-fourths or more of a tracer dose of radioiodine and quite physiologic fluctuations in the function of the kidneys or other tissues might modify significantly the quantity of radioiodine accumulated by the thyroid.

These considerations may account for the fact that, as judged by the comparative magnitude of the variations encountered in various states of thyroidal activity, neither the quantity of radioiodine in the thyroid at a selected time (12 hours) nor the asymptotic quantity in the thyroid (the thyroid fraction [5]) appears as significant as several other measures of iodine-accumulating function listed in Tables I and III. Measurements of the quantity of radioiodine in the urine, probably because they reflect the quantity in the thyroid indirectly, appear less significant.

Measurements of rates. Disappearance rate (2) reflects accumulation of radioiodine by the thyroid only indirectly, since it measures the disappearance of radioiodine as iodide from the blood into all tissues into which it goes, including kidneys and other tissues as well as thyroid. Disappearance rate varies from one group to another (Table I) by about the same degree as the quantity in the thyroid after 12 hours or the thyroid fraction (5).

Extrarenal disposal rate (4) is one step closer to a direct measure of iodine-accumulating function. It measures the disposal of radioiodine by all tissues other than the kidneys. Inasmuch as the thyroid is the most important of these, except in hypothyroid or athyroid persons, it appears to be a fairly reliable index of iodine-accumulation rate, subject only to inaccuracies resulting from variations in the removal of iodine by tissues other than the kidneys. It is perhaps somewhat paradoxical but nevertheless it appears to be true that extrarenal disposal rate, which is estimated from urine, appears a more valid measure of iodine-accumulating function in cases of normal or increased thyroid activity than direct estimation of the quantity of radioiodine in the thyroid. This is not the case when thyroid activity is reduced or absent.

The accumulation rate (7), estimated directly from serial observations *in vivo* or approximated from the curve of urinary excretion and a single observation *in vivo* during the period of iodine accumulation, appears to measure iodine-accumulating function *directly*, uninfluenced by variations in the function of the kidneys or of other tissues. Together with accumulation gradient it appears the most significant of the various measures enumerated in Tables I and III.

Accumulation gradient. The value which Stanley and Astwood (12) called "accumulation gradient" does not correspond either to disappearance rate or to accumulation rate as we have defined them, although it most nearly approximates the latter. The numerical value given to accumulation gradient is an arbitrary number without quantitative relation to the physiologic processes involved. Since it is a value obtained by dividing counts per second by a function of time, the numerical value of the accumulation gradient will vary with differences in the sensitivity of the counting apparatus, differences in the quantity of radioactivity given in the tracer and differences in the geometric relationship of counter to thyroid. These factors can all theoretically at least be corrected for, but it is likely that they will make it difficult to obtain figures in different laboratories which can be compared with one another. The mean value of accumulation gradient in the euthyroid cases shown in Table I is only about a third as large as Stanley and Astwood's figures, despite the fact that the values were corrected for both quantity of radioactivity and geometric relationship. This lack of agreement probably reflects differences in the sensitivity of the apparatus, and perhaps also a difference in the value of the microcurie employed as a standard.

The accumulation gradient has the great advantage that it can be obtained without continuing observations long enough to evaluate the asymptotic value of the accumulation curve. This advantage was employed by Stanley and Astwood to evaluate the antithyroid potency of various drugs under conditions which would have precluded direct estimations of iodine-accumulation rate, since the accumulation curve was modified by the addition of the drug a few hours after the experiment had been begun.

Significance of accumulation rate. The radioactivity contained in the tracer given to a patient initially may be regarded as labeling only the quantity of iodide given in the dose. Once sufficient time has elapsed for absorption to have occurred and for the dose of labeled iodide to reach equilibrium in the blood and the body fluids, the radioactivity in the tracer may be considered to label all of the iodine in the blood and body fluids which is in the same chemical form as the dose given (that is, as iodide). On this basis accumulation rate measures the proportion of all of the iodide in blood and body fluids which is being accumulated in the thyroid per hour. The iodine-accumulation rate of the thyroid is thus expressed in terms which are independent of the tracer dose given as well as independent of variations in the removal of iodine by other tissues, such as the kidneys.

Accumulation rate has a connotation somewhat similar to "clearance" as used in studies of renal function. It could be used interchangeably with clearance providing the volume of distribution of iodine in blood and in the fluids of the body in equilibrium with the blood did not vary significantly. Accumulation rate relates the iodine-accumulating function to the total stock of available iodide in the body as a whole. It is more reasonable to suppose, however, that this function is more directly related to the *concentration* of iodide in the blood circulating through the thyroid than to the total *quantity* of iodide in the blood and in distant parts of the organism which may be in equilibrium with the blood. Furthermore, it is likely that the volume of distribution of iodide may vary in different persons and in various pathologic conditions. For these reasons, *thyroidal iodide clearance*, expressed as the volume of plasma cleared of its iodide content per minute, may prove to be a more accurate measure of iodine-accumulating function than accumulation rate.

Accumulation rate is estimated from observations on the thyroid alone, whereas clearance of iodide by the thyroid must be derived from simultaneous observations on both thyroid and blood. Thyroidal iodide clearance can be obtained by multiplying accumulation rate by the volume of distribution of iodide, if the latter is known. In the absence of a measure of volume of distribution,

IODINE-ACCUMULATING FUNCTION OF THE THYROID

TABLE V
Comparison of accumulation rate, thyroidal clearance of iodine and volume of distribution of iodine

Case	Diagnosis	Basal metabolic rate	Iodine accumulation rate	Thyroid iodine clearance	Volume distribution of iodine	
		per cent	per cent/hour	cc./min.	total liters	cc./kg.
1	Adenomatous goiter without hyperthyroidism	-14	3.6	13.5	22.8	330
2	Adenomatous goiter without hyperthyroidism	-5	1.0	3.0	18.0	240
3	Adenomatous goiter without hyperthyroidism	+5	0.6	2.2	22.0	414
4	Exophthalmic goiter	+28	23.2	68.0	17.6	290
5	Exophthalmic goiter	+42	10.0	20.4	12.2	210
6	Exophthalmic goiter	+34	24.6	69.0	16.9	270
7	Exophthalmic goiter	+29	50.7	228.1	27.0	500
8	Exophthalmic goiter	+21	13.5	28.8	12.8	230

the thyroidal clearance of iodine may be estimated by a simple modification of the standard formula for renal clearance.⁴ In Table V are given values for thyroidal iodide clearance (determined directly) and iodine accumulation rates for eight cases in which both blood and thyroid data were available. Also given are values for the volume of distribution of iodine estimated from clearances and accumulation rates.⁵ It will be observed that

⁴The standard formula for renal clearance

$$\frac{\text{concentration in urine} \times \text{volume of urine}}{\text{concentration in blood}}$$

becomes $\frac{Q_t}{B}$ where Q_t is the quantity of radioiodine accumulated in the thyroid in an appropriate interval of time and B is the mean concentration of radioiodine in the blood during the same interval. Q_t is obtained by taking the difference between the quantity of radioiodine observed in the thyroid at the start of the interval and the quantity present at the end of the interval. Since the concentration of radioiodine in the blood decreases exponentially with time, the mean concentration of radioiodine in blood for the interval must be evaluated from the formula

$$B = \frac{B_1 - B_2}{\log_e B_1 - \log_e B_2},$$

where B_1 and B_2 are the observed concentrations at the beginning and end of the interval respectively. The clearances in Table V were all based on observations two and six hours after administration of the dose.

$$\text{Volume of distribution} = \frac{\text{clearance}}{\text{accumulation rate}} \times \frac{60}{1,000} \times 100$$

the clearances and the accumulation rates vary more or less proportionately in the cases studied, and also that the volume of distribution appears to be somewhat larger than the usual value for the volume of extracellular fluid in some cases. The fact that volume of distribution may vary considerably from case to case indicates that accumulation rate may not reflect clearance with complete fidelity and therefore may not be entirely accurate as an absolute measure of iodine-accumulating function. However, accumulation rate may be the most direct and quantitative measure of this function which can be determined from *in vivo* observations alone.

The nature of the iodine-accumulating function. It is important to note that the function of the thyroid appraised directly or indirectly by any of the measures which have been discussed is a very particular one; namely, the accumulation of iodine in the thyroid. Such accumulation probably reflects in large measure the formation of diiodo-tyrosine and thyroxine and their storage in the reservoir of the thyroid follicle.

If one could assume that the total quantity of iodine contained in the thyroid was more or less constant for any short period (that is, did not fluctuate rapidly), then accumulation rate might reflect the rate at which thyroid hormone was being secreted and perhaps might serve as an index of thyroid turnover rate. However, some of the earliest work of Hamilton and Soley suggests that there could be a dangerous fallacy in such assumptions. They observed in two cases of nodular goiters and hypothyroidism that despite clinical evidences which would lead one to infer that the secretion of thyroid hormone by the thyroid was inadequate or nil, the thyroids collected radioiodine in quantities similar to those collected in exophthalmic goiter. We have observed a similar disparity in certain myxedematous states accompanying thyroiditis and cyanotic goiter. Until more is known, therefore, it is probably best to regard iodine accumulation by the thyroid as a function which does not necessarily or invariably parallel the secretion of thyroid hormone.

The iodide-concentrating function measured by Stanley and Astwood (3) in the human thyroid blocked with mercaptoimidazol must be regarded as a thyroidal function involving iodine distinct

from iodine accumulation as the term has been applied here. The iodine concentrated by the blocked thyroid has been shown to be in the inorganic state and probably in some sort of equilibrium with the blood. The rather rapid decrease of thyroidal radioiodine observed in the blocked thyroid takes place at a rate roughly comparable to the disappearance of radioiodine from the blood as we have observed it in cases of myxedema. These considerations lead one to predict that the kinetic relationships shown to exist between radioiodine in urine, blood and thyroid in this and previous papers will not apply in the case of the phenomenon described by Stanley and Astwood.

Finally, it must be emphasized that the methods employed in this paper and the papers which have preceded it for the estimation of rates of disposal of radioiodine in urine, thyroid and other tissues are based on a model which is undoubtedly oversimplified. The values obtained may contain errors arising from factors which complicate the picture, such as the rate of absorption from the gastro-intestinal tract, the time required for equilibrium to become established between the blood and body fluids, and the rate of secretion of radioiodine from the thyroid once it has been accumulated. It is essential, therefore, to regard the values reported as at best first approximations. Nevertheless, the consistency with which independent observations on urine, thyroid, blood and peripheral tissues can be made to match one another in a simple scheme is some justification for assuming that the various interrelationships which have been discussed may be valid ones.

SUMMARY

An empirical method has been described for the measurement in microcuries of radioiodine collected by the human thyroid gland after oral administration.

The iodine-accumulation rate of the thyroid is defined as the proportional rate at which the thyroid accumulates iodine. Two alternative methods have been described for estimating this value. A basis has been given for assuming that this rate applies to all of the iodide in the blood and body fluids in equilibrium with the blood.

Mean iodine-accumulation rate by the thyroid was 2.4 ± 0.7 per cent per hour in five patients

having normal thyroid function and low-grade thyroid tumors, 4.6 ± 1.3 per cent per hour in seven patients having adenomatous goiter without hyperthyroidism and 20.2 ± 5.6 per cent per hour in seven patients having hyperthyroidism.

Accumulation rate has been compared with measurements of the quantity of radioiodine excreted in urine, the quantity collected in the thyroid and the disappearance rate of radioiodine from the blood. Accumulation rate appears to be a more significant measure of iodine-accumulating function of the thyroid than any of these.

The rate of extrarenal disposal of iodide, estimated from the curve of urinary excretion of radioiodine, closely reflects accumulation rate in cases of normal or increased thyroid activity. It appears in such situations to be a valid index of accumulation rate, despite some inaccuracy resulting from variations in the disposal of iodide by tissues other than thyroid or kidneys.

Accumulation rate may be less significant as a measure of accumulating function than thyroidal iodide clearance, determined directly from *in vivo* observations over the thyroid obtained simultaneously with determinations of the concentration of radioiodine in plasma.

THE VALIDITY OF THE ELECTROKYMOGRAPHIC METHOD FOR MEASUREMENT OF DIAMETER CHANGE OF THE AORTA AND PULMONARY ARTERY DURING CIRCULATORY DISTURBANCE¹

By CALVIN F. KAY, JAMES W. WOODS, JR., HARRY F. ZINSSER, JR.,
AND J. MALVERN BENJAMIN, JR.

(From the Robinette Foundation of the Hospital and the Moore School of Electrical Engineering, the University of Pennsylvania, Philadelphia)

(Received for publication April 20, 1948)

It has been demonstrated by Henny, Boone, Chamberlain, and their associates that border movements of the heart and great vessels may be recorded with the electrokymograph (1, 2, 4, 7). Confirmation of this work has been reported by others (3, 5, 6). Our studies were designed to investigate the accuracy with which movements of the aorta and pulmonary artery could be recorded with this instrument, and the significance of these movements as measures of dynamic cardiovascular changes during certain acute disturbances of the circulation. For these experiments, acute intrathoracic pressure variation was chosen as the implement for the production of circulatory disturbances. It is a procedure with which a new investigative method may be evaluated by comparison with observations of venous, arterial and pulmonary arterial blood pressure, cardiac output, roentgenokymography, and roentgenographic lung density in control studies or in the published reports of others.

The electrokymograph utilizes the roentgen ray beam of the fluoroscope. When the long axis of a small rectangle of fluoroscopic screen is placed perpendicular to the pulsating border of the heart or a great vessel, the average intensity of illumination of the whole rectangle will vary with the motion of the border. When movements of a great vessel are recorded, the dense shadow moves outward in systole to diminish the intensity and in diastole the reverse occurs. These changes in illumination, when viewed by a sensitive photoelectric tube, are converted to electrical impulses which are recorded by an electrocardiographic apparatus.

¹The Heart Disease Demonstration Section of the U. S. Public Health Service provided the apparatus and part of the funds for this study.

METHODS

Recording methods

The electrokymographic equipment used in this study was of the type described in detail elsewhere (1, 2). An alternating current direct-writing recorder manufactured by the Brush Development Company (8) was used instead of an optically recording string galvanometer. A single stage of amplification was inserted between the photo multiplier tube and the filter.

The response characteristics of the recording apparatus were investigated as a preliminary procedure. To test the frequency response, a circular lead disc was eccentrically mounted on the shaft of a variable speed motor. The edge of the disc was interposed in the X-ray beam perpendicular to and directly in front of the rectangular slot of the phototube. As the disc revolved, a sine wave was recorded.² The recorded wave amplitudes were then measured at varying motor speeds. The results are shown in Table I.

TABLE I

Frequency response of recording instruments, expressed in terms of percentage of amplitude at one cycle per second

Frequency	% amplitude
1	100
2	89
3	79
4	70
5	62
6	55
7	49
8	43
9	38
10	33
15	20
20	13

In a second procedure, the response characteristics of the direct-writing Brush instrument were compared with those of optically recording Cambridge and Sanborn instruments. Using the same eccentric cam, rotated at speeds from 1 to 75 cycles per second, with the original filter and also other filters with which the loss at higher

²The approximation to a pure sine wave is close enough for practical purposes. The mathematical analysis of the wave form generated by the eccentric cam will be presented in a subsequent publication (20).

frequencies was much less than with the original filter, less than 2% variation was recorded at any time between these three instruments, recording simultaneously.

A third procedure was devised to test the relative sensitivity of the various portions of the phototube slot. For this purpose, the phototube output was directly coupled through a potentiometer to a Cambridge string electrocardiograph. A lead sheet was interposed immediately in front of and perpendicular to the phototube slot. Starting with the slot completely exposed, the lead sheet was moved in successive 2 mm. steps (from base

toward free end of tube) until the slot was occluded. The magnitude of string deflection resulting from each 2 mm. movement of the lead sheet was then recorded and measured. The results are shown in Table II.

TABLE II

Relative sensitivity of various portions on the receptor slot of the phototube

Motion in cm.	Recorded amplitude in cm.
0.0-0.2	0.05
0.2-0.4	0.45
0.4-0.6	0.50
0.6-0.8	0.60
0.8-1.0	0.60
1.0-1.2	0.65
1.2-1.4	0.65
1.4-1.6	0.55
1.6-1.8	0.50
1.8-2.0	0.45
2.0-2.2	0.20
2.2-2.4	0.05

From these studies the following conclusions are drawn: (1) If a sine wave of fixed magnitude is impressed upon the phototube, the recorded amplitude is diminished by 50% when the frequency is increased from 1/sec. to 7/sec. and by 75% when the frequency is in-

creased from 1/sec. to 13/sec. (2) In response to any impulse having a sine wave frequency of from 1/sec. to 75/sec., the records obtained with the direct-writing Brush instrument are identical with those obtained with optically recording instruments. (3) The receptive slot of the photomultiplier tube is 2.4 cm. long. In the zone between 0.6 and 1.6 cm. from the tube-base end, the sensitivity is uniform with a maximum possible error of 15%. In the portion of the slot between 0.2 and 2.0 cm. the maximum possible error is 30%.

Investigative procedure

Ten healthy young adults were selected for this study. None had any symptoms or signs suggestive of heart disease or of pronounced vasomotor instability. The standard straining procedure, a modification of the Valsalva experiment, was performed in the sitting position. Braees were applied to the chest and shoulders to reduce extraneous movement. On command, breathing was arrested in a mid-respiratory position and the recording apparatus was set in motion. After a brief control period, the subject strained against a column of mercury to a pressure of 30 mm. This pressure was maintained for 15 seconds. He then relaxed for ten seconds before resuming respirations. The procedure was then repeated several times. The subject kept his glottis open throughout the experimental procedure.

Employing this standard procedure, electrokymographic tracings were recorded from the pulmonary artery and aortic knob. Intrapulmonic pressure was directly observed by the subject and operator, and recorded by a strain gauge and electrical recorder or capsule and optical recorder. Brachial artery pressure was recorded simultaneously through a Peterson catheter to a capacitance manometer (8, 9). In seven subjects, records were made with the vertical ballistocardiograph during the straining procedure. Representative tracings are shown in Figures 1-5.

In the electrokymographic records, an upward motion parallels outward motion of the great vessels during ejection; the downward curve follows the inward motion of the vessel during diastole. The intrapulmonic, arterial pressure, and ballistocardiographic curves are self explanatory.

RESULTS

The variations of pulse wave amplitude of the aorta and pulmonary artery, as recorded by the electrokymograph during and after the straining procedure, in each of the ten subjects, together with the results of control studies, are indicated in Table III.

Aortic pulsations

The pulse curves recorded from the aortic wall usually remained quite constant during the control period of respiratory arrest. A gradual decrease in amplitude began with the increase in intra-

* The procedure employed in obtaining these figures was technically faulty (see text).

Ten healthy subjects, aged 20 to 30. Amplitude of electrokymographic recorded pulsations of the aortic knob (AK), pulmonary artery (PA) during and after voluntary straining expressed in terms of percentage of control level. Diastolic pressure (DBP) and pulse pressure, simultaneously recorded from the brachial artery, are also expressed in terms of percentage of control level. Ratio of pulse pressure (Δp) to recorded amplitude of aortic pulsation (Δd) and beats/second are also shown.

bronchial pressure, and continued until straining ceased. Thereafter, the amplitude increased gradually for the first three or four beats, then rapidly increased to levels higher than in the control period. A pattern of this type was observed in eight of ten subjects. In two subjects (Nos. 5 and 8, see Table III), the amplitude after relaxation did not return to control levels. A technical error, to be discussed below, probably accounted for this.

Arterial pulse pressure

In measurements from the brachial artery, simultaneously recorded, the pulse pressure variations before, during, and after the straining procedure were, in general, parallel to the variations of aortic pulsation amplitude. The characteristic pattern of a fall in pulse pressure during the period of straining, a gradual rise after relaxation, followed by a wide pulse pressure in the later post-straining period, was observed in eight of the ten subjects. In the other two subjects (Nos. 2 and 5) the pattern was atypical only in that the amplitude in the post-straining period reached, but did not exceed, that of the control period.

Diastolic blood pressure

The diastolic blood pressure rose abruptly with the increase in intrabronchial pressure, and fell

when straining ceased. This phenomenon was the result of the transmission to the recording apparatus of pressure derived from the activity of the thoracic and abdominal muscles in raising intrabronchial pressure, and had no direct relation to that component of the recorded pressure derived from the pumping action of the heart. Under these circumstances it is customary to designate the recorded pressure as the *gross* pressure. Subtraction of the intrabronchial pressure from the gross pressure gives the *net* pressure, or that component of the recorded pressure which is dependent upon the activity of the heart. Note that no such correction was necessary for the electrokymographic recordings, since the intrathoracic pressure changes were exerted equally upon both sides of the vessels.

The net diastolic pressure fell rapidly during the first few seconds of straining in all individuals. A considerable rise toward or even above the control level was observed in a few individuals in the late period of straining; in others the fall was sustained. The first beat or two after straining showed little change. A rise above the control level then occurred in eight of the ten subjects.

Pulse rate

From the onset of straining the pulse rate steadily increased. Tachycardia persisted for several beats after relaxation, followed by the abrupt onset of bradycardia.

Pulmonary artery pulsations

Electrokymographic tracings from the pulmonary artery during the period of straining followed the same general pattern as was recorded from the aorta. A reduction in amplitude occurred in all subjects. At the moment of relaxation an important difference was characteristic. A large increase in amplitude regularly appeared immediately upon the return of intrabronchial pressure to the atmospheric level. The later rise above the control level was neither as great nor as consistent as in the aortic recordings. The electrokymographic records from the pulmonary artery resemble the pressure curves recorded by Lauson, Bloomfield and Cournand (10) and by Cournand (11) from the pulmonary artery during a similar straining procedure.

FIG. 6

Subject No. 1. Beat-by-beat amplitude of recorded pulsations of the aortic knob (AK) in mm. (scale B), simultaneously recorded with pulse pressure (PP) and gross diastolic pressure (DBP) in mm. Hg (scale B) and pulse rate (PR) in beats/minute (scale A). Amplitude of pulsations from the pulmonary artery (PA) during a repetition of the straining procedure is shown to illustrate especially the characteristic response in the immediate post-straining period.

Beat-by-beat graphic records from one subject of the magnitude of aortic pulsation with reference to simultaneously recorded pulse pressure, diastolic pressure, and intrathoracic pressure are shown in Figure 6. A similar record of the magnitude of pulmonary artery pulsation of the same individual during a repetition of the straining procedure is included especially to illustrate the major difference between aortic and pulmonary artery response in the immediate post-straining period.

Ballistocardiographic records

Most of the ballistocardiographic records of stroke volume in the sitting position during straining were technically unsatisfactory. The muscular activity necessary to increase voluntarily intrathoracic pressure invariably introduced artefacts into the records. A reduction of complex ampli-

tude was occasionally discernible, followed by large complexes when straining ceased (Figure 5). Application of the Starr formula for determination of stroke volume (12) was rarely possible. Previous ballistocardiographic studies of the stroke volume during straining (13-15) are not pertinent to this problem since the subjects were in the recumbent posture, whereas our subjects were in the sitting posture.

Analysis of results

Stroke change in relative diameter of the aorta and pulmonary artery could be accurately measured by the electrokymographic method if (1) the recorded curves bore a direct, linear relation to the actual movements of the vessel wall, and (2) if the pulsatile change in position of the vessel wall were a true measure of change in vessel diameter. From the data available it is

possible to estimate the degree to which we have approached this ideal.

The relation of recorded curves to vessel wall movements

The response characteristics of the recording apparatus introduced the characteristic imperfections of overdamping. From a study of the frequency response, shown in Table I, it is apparent that this factor must have had an important influence upon recorded wave shape. For example, it was shown that at a frequency of 10/sec., a sine wave of fixed magnitude is recorded only 33% as large as at frequency of 1/sec. If the wave manifested in the dicrotic notch were a sine wave with duration of 0.1 sec., the recorded amplitude would be 33% of that which should have been recorded. Since the wave is actually complex, and usually of shorter duration than 0.1 sec., the magnitude of recorded error is even greater. Other components of the wave pattern are undoubtedly at frequencies of 20/sec. or more. Thus, the finer details of wave shape were smoothed out in the recorded curves and the peaks of the major components were flattened. Some of the differences in wave shape between the recorded aortic curves and the brachial pulse curves (*e.g.*: curves during the late straining period in Figure 1) cannot be explained on the basis of overdamping of the apparatus. Actual differences in wave forms of the two vessels must have been a factor of appreciable importance.

For the comparison of relative amplitudes of recorded waves during the various periods of the straining procedure, overdamping of the degree indicated in Table I should not be expected to introduce a large discrepancy. The duration of the ejection phase of systole in the normal individual with a pulse rate of 1/sec. is 0.25 sec. (16). The curve approximates a half sine wave, therefore the sine wave duration would be 0.5 sec. or a frequency of 2.0/sec. By a similar calculation, the sine wave frequency of systolic ejection at a pulse rate of 2/sec. is 3.0/sec. Although figures are not given, by extrapolation of the curves, the frequency at a pulse rate of 3/sec. is calculated at about 4.0/sec. By calculation from data provided in Table I, it is found that a loss of 19% in recorded amplitude results from

a frequency change of this magnitude. Insofar as the wave patterns of systolic ejection differ in shape from a half sine wave, the loss would be somewhat greater. Since systole ends before the inscription of the last portion of the half sine wave, the loss would be somewhat less. It seems justified to conclude that in these studies, the additional loss in recorded amplitude resulting from the increased pulse rate itself was not greater than 30%, and that amplitude changes of this magnitude, or even of considerably less than this magnitude when pulse rate was taken into consideration, could be considered significant.

In Table II it was shown that the sensitivity of the middle third of the phototube slot was approximately linear. It was usually easy to so place the subject that the shadow of the vessel wall remained in this zone throughout the straining procedure. Hence, non-linearity of the receptor apparatus was not ordinarily an important source of error. Reference was made above to atypical aortic response patterns in subjects Nos. 5 and 8 (see Table III). In reexamining these tracings, it was found that the individual wave patterns were distinctly bizarre in form, with long, flat crests. This pattern was not observed in any other individual studied. It was subsequently demonstrated that similar waves could be produced by allowing the shadow of the pulsating vessel to extend in systole beyond the sensitive portion of the receptor slot. The unusual results in these two individuals are therefore attributed to this technical error. Such faulty technique should be readily avoided and easily recognized when it occurs.

The relation of vessel wall movements to stroke change in diameter

This problem is difficult to subject to objective, quantitative study. Presumptive evidence is offered in several observations. If vessel expansion and contraction were equal in all diameters and the center of the vessel remained fixed, as in Figure 7A, motion of the wall would be in exact proportion to the change in vessel diameter. Even if one side of the vessel were fixed, as in 7B, the same would hold true. If, however, the center of the vessel moved erratically, as in 7C, movement of the vessel wall would be a very inexact measure of the diameter change. Several

FIG. 7. THE EFFECTS OF LATERAL DISPLACEMENT OF A VESSEL UPON THE CONTOUR OF RECORDED CURVES (UPPER FIGURES)

The cross-hatched rectangle represents the slot of the phototube. Numbers indicate position of the vessel wall at various moments of the pulse cycle.

observations suggest that lateral displacement of the entire vessel was not a major factor in the pulse waves recorded. (a) Respiratory movement undoubtedly causes lateral movement, but this is slow, tending to cause displacement of the entire baseline, which is continuously compensated by the time constant of the apparatus and hence does not greatly influence the amplitude or shape of the individual complexes. In our studies respiration was arrested during the recording period. (b) Rocking motions of the base of the heart might be expected to cause rhythmic lateral displacements of the great vessels. In assessing this factor, a comparison of curves from the left side of the aortic knob with those from the right side of the ascending aorta is of little value, since the differences between the records can evidently be accounted for by the effects of superior venacaval pulsations upon the records from the ascending aorta (6, 7). However, the curves recorded from the aortic knob and from the pulmonary artery invariably show changes in amplitude which correspond qualitatively and to a considerable degree quantitatively with changes in pulse pressure in the respective vessels. If lateral displacement were an important factor, wave motions completely unrelated to pressure changes would be expected. Furthermore, pulsations of large amplitude were regularly recorded from the pulmonary artery in the immediate post-straining period, during which aortic pulsations

were very small. Hence, the motions of the two vessels appear to be independent, each related to the pressure change within the respective vessel, and not a function of a rocking motion of the base of the heart.

In view of these observations, it seems reasonable to conclude that the electrokymographic tracings recorded from the pulmonary artery and aortic knob provide a measure of the relative diameter changes of these vessels resulting from changes in intrinsic vascular pressure. It is obvious that changes in pulse pressure (Δp) should result in changes in aortic cross sectional diameter (Δd). In our studies this was found to be true, but the ratio of pulse pressure to aortic pulsation magnitude ($\Delta p/\Delta d$) varied by as much as 50% in the separate beats of a single individual during a straining procedure (see Table III).

The relation of aortic volume change (Δv) to pressure change (Δp) has been demonstrated by Hallock and Benson (16) in studies of excised human aortas. In individuals of the age group of our subjects (20–30), $\Delta p/\Delta v = k$ where pressures are in the physiologic range. The expression $(\Delta v/\Delta p)V = k$, as employed by Wiggers (17), is essentially the same, since V is a fixed value for each individual tested: namely, the aortic volume at a specified mean pressure.

Katz and his associates (18) found considerable discrepancy between the pressure-volume relationships of the aortas of intact, living dogs

as compared with the same aortas after death. They injected diodrast directly into the aortas and computed aortic volume from the X-ray shadows of films taken at varying levels of blood pressure. Wiggers and Wégria (19) measured changes in aortic diameter directly, with a clamp aortagraph. As in our studies, $\Delta p/\Delta d$ relationships in the separate beats of a single subject showed considerable variation. An inspection of their illustrations shows $\Delta p/\Delta d$ to be 1.0 and 1.4 in beats (y and y of Figure 4, Wiggers and Wégria [19]) of the same approximate pulse pressure and diastolic blood pressures, measured by the technique which we have employed. One would not expect pressure-diameter relationships to exactly parallel pressure-volume relationships. A rough estimate of aortic diameter change to aortic volume change may be deduced as follows:

(1) The relation of aortic diameter change to aortic cross sectional area change approaches linearity. If aortic diameter were 2.0 cm. at a given diastolic pressure, and a unit of systolic pressure increment increased the diameter to 2.1 cm., the resulting increase in aortic area is from 1.0π cm.² to 1.1025π cm.². An area change of ten times this magnitude (1.0π cm.² to 2.025π cm.²) is accomplished with a diameter change to 2.846 cm. Therefore, within the physiologic range specified, diameter change is a linear function of area change within the degree of error in the equation $.1/1 = .846/10$, or about 15%.

(2) Area change would be a linear function of volume change if lengthening were not a factor, but the latter is actually of relatively minor importance. Thus, if in increasing the aortic area from 1.0π cm.² to 2.0π cm.², the aorta were increased in length from 100 cm. to 106 cm., area would be a linear function of volume within the margin of error in the equation $100/1 = 212/2$, or about 6%.

(3) Thus, change in aortic diameter (Δd) appears to be a reasonable approximate linear function of change in aortic volume (Δv). Thus, if $\Delta p/\Delta v = k$, then $\Delta p/\Delta d = k$ should be reasonably accurate.

From the investigations of others, cited above, a roughly linear relationship between change of pressure and change of diameter should have been expected in our subjects. It will be noted that the value of $\Delta p/\Delta d$ is consistently relatively low during the late post-straining period and high during the period of straining. The pulse rate is seen to parallel the values of $\Delta p/\Delta d$. As shown above, the recorded wave amplitude is seen to bear a direct relationship to the pulse rate because of the technical characteristics of the re-

cording apparatus. This technical defect exerts an influence in the direction of the results. The range in results of $\pm 50\%$ in the ratio $\Delta p/\Delta d = k$ is beyond the estimated maximum of 30% error in the response characteristics of the apparatus. A description of certain alterations of the instrument which have resulted in improved linearity of frequency response is now in preparation (20). With such a correction, and with allowances for the differences in wave forms in the aorta as compared with the brachial artery, it seems probable that the variations of $\Delta p/\Delta d$ ratio which we have recorded during acute circulatory disturbance reasonably approximate the actual pressure-volume relationships in the aortas of the individuals studied.

Discussion of the physiologic response to intrathoracic pressure change

The effects of transient increase of intrathoracic pressure, produced by voluntary straining, upon cardiovascular dynamics have been studied intensively by many methods (10, 11, 13, 21-29). The differential pressures in the various heart chambers and great vessels, stroke volume, the distribution of blood mass, and the pulse rate have been shown to be influenced. Interpretation of these data has led to the following conclusions. Increase in intrathoracic pressure is accompanied by a comparable increase in intra-abdominal pressure and results in: (a) An immediate reduction of blood return to the heart from the periphery, with resulting increase in peripheral venous pressure. The blood return from the abdominal viscera is little if at all impeded. (b) The right heart output is consequently reduced with resulting fall in net pressure in the right ventricle and pulmonary artery. (c) The pulmonary blood reservoir is progressively exhausted with reduction in opacity to roentgen rays and subsequent reduction of blood return to the left heart chambers. This is followed by (d) reduced stroke volume of the left ventricle and by reduced pulse pressure and net systolic and diastolic pressure in the systemic circulation with reflex peripheral vasoconstriction and tachycardia. The return of intrathoracic pressure to the atmospheric level is accompanied by a rush of blood into the thoraco-abdominal cavity and right auricle, a sudden marked increase in right heart

output and in pulmonary artery pulse pressure and blood pressure, restoration of the pulmonary blood volume and blood return to the left heart, and restoration of stroke volume, pulse pressure, and systemic blood pressure. In the post-straining period a transient hypertension is normally observed as the result of normal or above-normal cardiac output and persisting peripheral vasoconstriction. A sudden bradycardia regularly occurs as the aortic reflexes respond to this stimulus. All of the cardiovascular functions characteristically return to normal within one or two minutes.

From a careful examination of electrokymographic records alone, most of these physiologic disturbances can be deduced.

SUMMARY

1. Pulsatile movements of the aorta and pulmonary artery were electrokymographically recorded before, during, and after increased intrathoracic pressure produced by voluntary straining. The records obtained were compared with simultaneously recorded brachial artery pressure and with the reported observations of pulmonary artery pressure by others. Ballistocardiography as a control procedure was found to be unsatisfactory.

2. The response characteristics of the electrokymographic apparatus were studied as a preliminary procedure. The sensitivity of the various zones of the receptive slot of the phototube was found to be approximately linear. The frequency response of the apparatus resulted in the characteristic wave shape deformities of an overdamped system. During the various phases of the straining procedure, comparative recorded wave amplitude was sufficiently influenced by this technical factor to necessitate a correction of results for pulse rate.

3. A measure of relative stroke change in diameter of the aorta and pulmonary artery was recorded. Qualitatively these changes were respectively parallel to coincident changes in pulse pressure in the brachial artery in control studies and pulmonary artery in the reported observations of others.

4. The recorded amplitude of aortic pulsations, after correction for pulse rate, bore a quantitative relationship to pulse pressure approximating that

which would be expected between aortic diameter change and pulse pressure.

CONCLUSIONS

From a study of the movements of the aorta and pulmonary artery by the electrokymographic method, most of the cardiovascular disturbances produced by straining may be deduced. Although the measurements are quantitative only in a relative sense, the dynamic changes in the circulation are clearly recorded. This method may provide a useful substitute for direct manometric measurements with catheters in studies in which absolute quantitative measurements of intraaortic and intrapulmonic artery pressures are not necessary. It is a rapid, painless, and easily performed procedure suited to the study of the effects of a cardiovascular stimulus upon each of a large group of subjects. Certain limitations of the value of this method, imposed by the response characteristics of the apparatus in its present form, have been described. From the accuracy with which the nature of the cardiovascular disturbances produced by straining may be deduced from the electrokymographic records alone, the possible application of this method to other studies is implied.

We wish to express our appreciation to Drs. C. C. Wolferth and H. C. Bazett for their many helpful suggestions and to Dr. L. H. Peterson, Dr. K. F. Eather and Dr. J. L. Wiley for their invaluable assistance in the arterial pressure measurements.

STUDIES OF THE ROLE OF THE LIVER IN HUMAN CARBOHYDRATE METABOLISM BY THE VENOUS CATHETER TECHNIC. I. NORMAL SUBJECTS UNDER FASTING CONDITIONS AND FOLLOWING THE INJECTION OF GLUCOSE¹

By PHILIP K. BONDY,² DAVID F. JAMES, AND BETTY W. FARRAR

(From the Department of Medicine, Emory University School of Medicine, and the Medical Service, Grady Hospital, Atlanta, Georgia)

(Received for publication September 3, 1948)

Previous observations on the role of the liver in carbohydrate metabolism have been made entirely in animals. Recently a method has been developed for obtaining specimens of hepatic venous blood and estimating the hepatic blood flow in human beings (1). This has supplied a tool which makes possible direct investigation of the activity of the liver during various phases of carbohydrate metabolism in man. The present paper deals with the application of this technic to the study of the response of the liver to the fasting state and to the intravenous injection of glucose solution.

METHODS

Hepatic blood flow was estimated by the bromsulfalein method of Bradley (1) in some cases and in others by the urea method of Myers (2). In the few cases where blood flow determinations were not done, it was assumed that the hepatic blood flow was equal to the mean found in our other patients.

The hepatic vein was catheterized by a radiopaque catheter inserted through the right antecubital vein and guided under fluoroscopic observation. The tip was placed centrally in the right lobe in such a position that a free flow of blood could be obtained on aspiration. Occasional checks of position were made during the course of the procedure and at the end of the test period. Bradley (1) has shown that the bromsulfalein extraction may vary from place to place in the same liver. This results in some variation in the estimated hepatic blood flow. In the present study, where serial observations were compared, this type of variation was minimized by keeping the catheter tip in the same location throughout the procedure. At least 5 ml. of blood were withdrawn from the catheter and discarded before samples were withdrawn in order to avoid the possibility of dilution of the sample by saline remaining in the catheter. Peripheral venous and arterial samples were obtained

through indwelling Cournand needles usually placed in the left antecubital vein and the left femoral artery.

Glucose (0.5 gm./kg.) was administered intravenously in 250 ml. of distilled water over a period of 15 minutes.

Blood samples were obtained simultaneously from the artery and hepatic vein before injection and 15, 45, and 60 minutes after the beginning of the infusion. The samples were taken into a sodium fluoride-oxalate mixture and were promptly treated to obtain the necessary filtrates. Glucose determinations were performed by the method of Nelson (3) using a 1:10 zinc hydroxide filtrate. In our laboratory this method has had a standard error of ± 1.0 mg./100 ml. at a level of 100 mg./100 ml. Blood urea was determined on a 10% tungstic acid blood filtrate by the xanthidrol precipitation technic of Engel and Engel (5) and also on a 1:200 dilution of urine. With this method, the standard error of the urea determination was 0.1 mg./100 ml. at a level of 20 mg./100 ml. All determinations were read on a Lumetron photoelectric colorimeter.

CLINICAL MATERIAL

The subjects of these experiments were 15 essentially normal volunteers who were convalescing from acute diseases. All were well nourished and had been on a diet supplying more than 200 gm. of carbohydrate for at least three days prior to the procedure. The subjects were fasted for 18 hours before the tests. In some cases 0.1 or 0.2 gm. of nembutal in 50 ml. of water was given orally about 30 minutes before the procedure. Every attempt was made to keep the subjects comfortable. Venipunctures and arterial punctures were done under procaine local anesthesia. The patients were usually at ease, and most of them dozed during the course of the experiment. As a result of the precautions taken, it seems unlikely that the normal physiological reactions to pain, fear, or anger significantly affected the observations.

CALCULATIONS

The arterio-hepatic venous difference (A-HV) in mg./100 ml. is obtained by subtracting the hepatic venous from the arterial concentration. When the concentration is higher in the hepatic venous blood than in the arterial, the result is a negative quantity, indicating that the liver was losing the substance into the circulation. Where the A-HV value is positive, the liver was retaining the sub-

¹ Presented to the Southern Society for Clinical Research, New Orleans, La., January 27, 1948.

² Present address: Department of Physiological Chemistry, Yale University School of Medicine, New Haven, Connecticut.

stance, either by storing it (*e.g.*, glucose as glycogen) or by metabolizing it.

The hepatic venous system drains not only the liver but also the gastrointestinal tract and the spleen. Strictly speaking, therefore, the value for A-HV represents splanchnic rather than hepatic metabolism. This is discussed below.

An attempt has been made to estimate the amount of glucose formed from protein in the liver, on the basis of the amount of urea released. Using Shaffer's (6) data for the G/N ratios in diabetic dogs, it was assumed that the release of 1 gm. of nitrogen as urea represented the deamination of a sufficient quantity of amino acids to supply 3 gm. of glucose. On this basis 1 gm. of urea is equivalent to 1.4 gm. of glucose. The validity of this calculation is discussed below.

The total splanchnic metabolism is obtained by multiplying the value of A-HV by the estimated hepatic blood flow, expressed as hundreds of milliliters per minute. Myers has shown (7) in man that the injection of glucose solution intravenously at a rate comparable to that used in these observations produces a mean decrease of hepatic blood flow of $10 \pm 3\%$ during the first hour after the infusion. This minor alteration of hepatic blood flow has been disregarded in our calculations.

RESULTS

Hepatic blood flow: Estimations of the hepatic blood flow fell well within the range of normal

as determined by Bradley (1) and by Myers (2) who found mean hepatic blood flows of 865 ± 24 and 800 ± 71 ml./min./M², as compared with 851 ± 71 ml./min./M² in this series (Table I).

Fasting hepatic glucose production: The splanchnic circulation contributed a mean of 3.5 ± 0.7 mg. of glucose per kilogram per minute to the circulation under fasting conditions (Table I).

Fasting hepatic urea production: The mean rate of urea production was found to be 0.21 ± 0.5 mg./kg./min. This may be considered a reflection of the rate of deamination of amino acids and, therefore, it provides a rough estimate of the rate of gluconeogenesis. The urea excreted may be expressed as estimated equivalents of glucose formed. Under fasting conditions the glucose formed from protein represents $7.3 \pm 1.0\%$ of the total hepatic glucose output (Table I). There was no relationship between the glucose output or the blood glucose concentration and the rate of urea production.

The effects of intravenous glucose: After the administration of 0.5 gm. of glucose per kilogram intravenously over a period of 15 minutes, a rise

† These samples were taken five minutes after termination of the glucose clysis.

in the arterial glucose level occurred. This gradually fell after the termination of the clysis until it reached normal levels. The shape of the arterial glucose tolerance curve indicated a normal carbohydrate metabolism in all cases (Table II).

The fasting hepatic venous glucose level was higher than the arterial in all cases except one (Table II, J. C. B.). There is no ready explanation for the inconsistency of this single observation.

Fifteen minutes after the clysis was begun, the hepatic venous glucose level was lower than the arterial in all but two cases (Table II, M. B. and L. W.). In these instances, technical difficulties caused a delay in obtaining the samples so that they were not collected until five minutes after termination of the clysis. At this time the arterial glucose level had begun to fall. It seems possible that an outpouring of glucose from the liver, stimulated by the sudden drop of arterial glucose concentration, might account for the negative values of A-HV in these cases.

At 45 minutes after the beginning of the infusion, more than half of the patients had negative value for A-V, and the mean A-HV was not significantly different from zero. At this time the mean arterial glucose level was 175 mg./100 ml. In some subjects, therefore, the liver began to give up glucose at a time when the arterial glucose level was still elevated. Such a

response suggests that regulation of the splanchnic glucose balance may depend partly on the rate of fall of the glucose level in addition to the absolute glucose concentration in the blood.

At 60 minutes the tendency to release glucose from the liver into the peripheral circulation was more marked. At this time, however, the patients were reacting with less uniformity than during the periods immediately after the injection. This

FIG. 1. ARTERIAL AND HEPATIC VENOUS GLUCOSE LEVELS, FASTING AND AT FREQUENT INTERVALS AFTER THE INTRAVENOUS INJECTION OF 0.5 GM. OF GLUCOSE PER KILOGRAM OVER A 15-MINUTE PERIOD

Note the intermittent retention and release of glucose by the splanchnic system during the descending portion of the curve.

FIG. 2. ARTERIAL AND HEPATIC VENOUS GLUCOSE LEVELS AND ESTIMATED HEPATIC GLUCOSE BALANCE AFTER THE INTRAVENOUS INJECTION OF GLUCOSE IN A HUMAN SUBJECT (LEFT) AND A DOG (RIGHT)

Balance values plotted above the zero line represent retention of glucose, and below the line represent release of glucose by the splanchnic system. The data for the dog are reproduced by permission of Dr. Soskin (8).

is reflected in the relatively large standard error for A-HV.

The observation that the splanchnic system could release glucose even in the face of high blood glucose concentrations suggested that the determining factor might be the rate of fall of the glucose level. To test this, one experiment was done in which samples were collected at frequent intervals. The curves obtained are shown in Figure 1. In this subject the hepatic venous concentrations fluctuated widely around the arterial curve. The significance of these data is discussed below.

The total glucose balance can be calculated by multiplying A-HV by the hepatic blood flow. This has been done for patient B. B. and plotted, together with the arterial and hepatic venous curves, in Figure 2. For comparison an experiment of the same sort in a dog, reported by Soskin *et al.* (8), has been plotted in the same figure. In order to avoid superimposition of the curves, negative balances have been plotted above the double line and positive balances below. The greater excursion of the glucose curve in the dog is probably due to the fact that 1.75 gm. of glucose per kilogram were injected in five minutes, whereas in the patient 0.5 gm. per kilogram was injected in 15 minutes.

The peripheral venous glucose levels were invariably lower than the arterial and were usually lower than the hepatic venous levels under fasting conditions. After the infusion the venous level rose less sharply than did the arterial or hepatic venous concentrations. During the declining phase of the curve, the fall of the venous level was also less rapid. As a result, the concentration of glucose in the peripheral venous blood was usually higher than in the arterial or hepatic venous blood by the end of the observation period. These relationships are shown for a typical case in Figure 3.

DISCUSSION

The hepatic venous system drains not only the liver but also the gastrointestinal tract and the spleen. Strictly speaking, therefore, the value for A-HV represents splanchnic rather than hepatic metabolism. Unfortunately, there is no method available at present for obtaining portal blood in the intact human being. By keeping our subjects basal we have hoped to reduce the metabolism of the extra-hepatic tissues in the splanchnic system to a minimum, and thus achieve a close approximation of the activity of the liver itself. It is possible to estimate the magnitude and direction of the error introduced in the study of hepatic metabolism by our inability to obtain portal ve-

FIG. 3. ARTERIAL, PERIPHERAL VENOUS AND HEPATIC VENOUS GLUCOSE VALUES BEFORE AND AFTER THE ADMINISTRATION OF 0.5 GM. OF GLUCOSE I.V. OVER A PERIOD OF 15 MINUTES

nous blood. Under fasting conditions in man, Sherlock and Walshe (9) and Ravault *et al.* (10) have shown that the portal glucose level is the same as that of the peripheral venous blood. London (11) found a consistently lower concentration of glucose in the portal vein of the dog than in the arterial blood. Since the portal blood contains less glucose than the arterial in the fasting subject, the amount of glucose released by the liver is actually greater than is indicated by the value of A-HV. The data of Soskin *et al.* (8) and of Lipscomb and Crandall (12) may be recalculated to determine the error introduced by using only the arterial and hepatic venous values. Under fasting conditions, the difference between the glucose production estimated from arterial and hepatic venous blood alone and that estimated from arterial, portal and hepatic venous blood, was less than the standard error of the glucose determinations in eight instances. There was a significant difference in two instances. In each case, where a difference occurred the value obtained from A-HV was lower than that from combined portal and arterial blood. After the intravenous administration of glucose to the dog of Soskin *et al.* (8), however, the error rose so that it was significant in every period, averaging 28.9% of the actual value. In every case, the value obtained by the use of A-HV was lower than that obtained using both arterial and portal blood.

In the basal human subject, therefore, it seems probable that values obtained by the methods we have used are quite close to the true hepatic metabolism, although tending to be somewhat lower. After the injection of glucose, it is less accurate to speak of our results as indicating liver metabolism. Even in this case, however, the error is consistent and the major fluctuations introduced are due to the activities of the liver. With these reservations, therefore, we have used the terms "splanchnic" and "hepatic" interchangeably.

The data obtained from normal human subjects agree in all particulars with the observations made on experimental animals. The mean rate of glucose production in the fasting human being (3.5 ± 0.7 mg./kg./min.) falls within the range observed in dogs. Lipscomb and Crandall (12), studying dogs by a method comparable to the

technic we have used, found a mean glucose production of 2.0 ± 0.2 mg./kg./min. In their review of the literature they found reported values obtained by various methods, varying from 1.0 to 4.2 mg./kg./min. in the dog. Bouckaert and deDuve (13) have recently reported a value of $4.0 \pm .75$ mg./kg./min. as the amount of glucose which must be infused to maintain the blood glucose level of a hepatectomized dog. They interpret this figure as equivalent to the amount of glucose released by the normal liver. It is of interest that the mean hepatic blood flow is less in man than in the dog (23 ± 1.5 ml./kg./min. for the human, versus 32 ± 2.2 ml./kg./min. for the dog [12], $p < 0.01$). The fact that the glucose output is equivalent suggests that a larger amount of glucose is released per milliliter of blood traversing the splanchnic circulation in man than in the dog.

Since the rate of release of glucose to the peripheral circulation may be considered as equivalent to the rate of utilization (combustion plus storage as glycogen or fat) of glucose in the peripheral tissues, our patients were utilizing glucose at a mean rate of 3.5 mg./kg./min. This is equivalent to 0.014 cal./kg./min. If calculated on the basis of calories per square meter of body surface, the mean rate of glucose release from the liver accounted for $.459 \pm .094$ cal./M²/min. This represents a mean of $70 \pm 13.9\%$ of the normal basal caloric requirement, calculated from the data of Dubois and Aub, for our patients. Since no direct measurement of the metabolic rate of the subjects was made, it is unwarranted to assume that the glucose output represented 70% of the actual metabolic requirement at the time of the observations. In three cases the rate of glucose production was higher than the total "normal" basal metabolic requirement (Table I), suggesting either that the subjects may not have been basal or that their basal metabolic rate may have been abnormal.

The conversion of urea production into equivalents of glucose production can only be a rough approximation of the true value. It has been estimated that the amount of glucose produced from protein might, under circumstances of maximal conversion, give rise to a G/N ratio as high as 8.0 (4). In order to determine the maximum amount of glucose which could have been re-

leased as a result of the observed rate of urea production, one would have to multiply the figures in Table I by a factor of 2.67. Even under these circumstances, however, the portion of glucose produced by the liver from protein breakdown would be only $19.7 \pm 2.7\%$.

The finding of negative values for A-HV at times when the arterial glucose value was still high is not in agreement with observations by Soskin *et al.* (8) in the dog. These observers found that the hepatic glucose balance did not become negative until the arterial glucose level had fallen to control levels. There are certain differences in the technics used which might account for the lack of agreement. The dogs utilized by Soskin were anesthetized and had been subjected to extensive surgical procedures, whereas the patients we were observing were in an essentially normal state. It is therefore possible that the animals observed by Soskin were not so sensitive to changes in the blood sugar level as were the human subjects. The fluctuations observed in A-HV can be explained by postulating that the hepatic glucose balance is sensitive both to the arterial glucose level and to the rate of fall of the glucose concentration. The influence of the rate of fall of the arterial glucose concentration may be partly mechanical, since a sudden fall of the intravascular concentration of dextrose would cause a diffusion of extracellular glucose back into the sinusoids, thus producing a negative value for A-HV.

It therefore seems probable that the rate of fall of the arterial glucose level plays a part in regulating the release of carbohydrate from the liver. This is well illustrated in the single case in which samples were obtained every ten minutes. Thus the liver, by intermittently releasing glucose to the circulation, brakes the descent of the blood glucose concentration and protects against the development of hypoglycemia.

It was noted that the peripheral venous glucose levels tended to be somewhat lower than those of the corresponding hepatic sample. This indicates that the peripheral tissues remove more glucose per milliliter of blood supplied to them than does the liver. No statement can be made regarding the relative total amounts of glucose involved, however, since no measurements of the

blood flow through peripheral tissues were attempted. After the injection of large amounts of glucose, the rate of fall of the arterial glucose concentration was greater than that of the peripheral venous content, so that toward the end of the period of observation many patients had higher venous than arterial levels. This can probably be explained entirely on the basis of diffusion of glucose from the intercellular tissue spaces back into the peripheral venous system as the arterial glucose level fell below the concentration of the substance in the interstitial fluids.

SUMMARY AND CONCLUSIONS

The hepatic catheterization technic has been used in studying the role of the normal human liver in carbohydrate metabolism both in the basal state and after the administration of glucose intravenously. Under fasting conditions, the splanchnic system releases glucose to the circulation at a mean rate of 3.5 ± 0.7 mg./kg./min. Of this, approximately 7% can be accounted for on the basis of gluconeogenesis from protein. The hepatic glucose production could account for a mean of 70% of the total normal basal metabolic requirement of the patients.

After the administration of glucose by vein, there is an immediate retention of glucose by the liver. Subsequently, as the arterial glucose level falls, glucose is released from the splanchnic circulation. The stimulus for this release appears to be both the arterial glucose level and the rate of fall of the glucose concentration. Evidence was obtained of the release of glucose from the liver at a mean arterial glucose level of 175 mg./100 ml.

It appears that the carbohydrate metabolism of the normal human being is similar to that of experimental animals on which previous studies have been made.

METABOLIC STUDIES ON PROTEIN-DEPLETED PATIENTS RECEIVING A LARGE PART OF THEIR NITROGEN INTAKE FROM HUMAN SERUM ALBUMIN ADMINISTERED INTRAVENOUSLY^{1,2}

By CHRISTINE WATERHOUSE,³ SAMUEL H. BASSETT,⁴ AND JACOB W. HOLLER,⁵ WITH THE TECHNICAL ASSISTANCE OF KATHRYN Y. CUSSON

(From the Department of Medicine, University of Rochester, School of Medicine and Dentistry, and the Medical Clinic of the Strong Memorial and Rochester Municipal Hospitals, Rochester, N. Y.)

(Received for publication September 22, 1948)

I. INTRODUCTION

Protein depletion has long been recognized as detrimental to many bodily functions. The problem is particularly urgent in the chronically ill patient who is unable to ingest an adequate caloric or protein intake. During the past decade the search for parenteral substitutes for oral protein has proceeded apace, although frequently without due regard for the fact that retention of nitrogen can be expected only when a certain critical caloric intake supplement has been made available in the form of carbohydrate and fat (1-3).

Mixtures of the essential amino acids, protein hydrolysates, and human plasma have been used with some success (4-6). All, however, possess certain disadvantages. Protein hydrolysates and synthetic amino acid preparations may give rise to vomiting and other reactions; also the rapidity with which they are deaminated and excreted in the urine suggests that they are poor sources of

nitrogen (4, 6). Plasma, especially when derived from large pools, may carry serum jaundice; and its relatively high content of sodium is also a source of difficulty in patients who tend to collect edema. Moreover, the utilization of intravenously administered plasma protein has been the subject of some controversy during the past few years. It is generally conceded that positive nitrogen balances can be established in both animals and man by the intravenous administration of homologous plasma, provided that the dose is in excess of the minimum protein requirements. It is felt by some investigators (7, 8) that the positive balance obtained is an illusory affair and that the actual utilization is poor in some instances. On the other hand, Whipple and co-workers (9) believe that parenteral plasma protein can supply all the requirements for maintenance over a considerable period of time. This implies that there is an exchange between the tissues and the injected protein and that this exchange satisfies the need of endogenous metabolism.

When purified human serum albumin became available in large quantities through the Red Cross program, it was recognized to have certain advantages over other materials in common use. Briefly these are: its low content of sodium, the general freedom from reactions when given intravenously in moderate amounts, and the fact that it can be prepared free from the hazard of viral jaundice. It carries the stigma, however, of being deficient in both tryptophane and isoleucine (10, 11). This deficiency has been partially rectified by the inclusion of acetyltryptophane as a stabilizer. Yet in view of the reported deficiencies, studies on the nutritive value of albumin for man should be pertinent. Eckhardt and others (12) were unable to maintain nitrogen balance when

¹ Part of this work was carried out under a contract between the University of Rochester School of Medicine and Dentistry and the Atomic Energy Commission. Partial support was received from the Committee on Growth, National Research Council, acting for the American Cancer Society, and from the Hochstetter Fund of the University of Rochester School of Medicine and Dentistry.

² The albumin used in these studies was prepared by the American National Red Cross from the blood of voluntary donors. This material has been supplied to investigators by the American Red Cross as part of its National Blood Program. The opinions and conclusions are those of the authors and do not necessarily reflect the policy of the National Blood Program.

37.5 Gms. of albumin a day, administered orally together with an adequate caloric intake, were the sole source of protein. Supplements of dl tryptophane and dl isoleucine did not improve utilization. However, when 50 Gms. of albumin were given, nitrogen was retained. Two patients were maintained in positive balance on 37.5 Gms. of albumin daily when the albumin was given intravenously. They concluded that albumin could maintain nitrogen equilibrium in man when given either orally or intravenously in sufficient amounts and that supplements of tryptophane or isoleucine were unnecessary. It should be recalled, however, that maintenance of equilibrium, or positive nitrogen balance, in short periods of this sort is quite a different problem from satisfying growth or maintenance requirements over a long period of time.

Albright *et al.* (13) have offered indirect evidence for the utility of injected albumin or plasma protein in protein nutrition. In a study of hypoproteinemic patients they found retention of a sufficient quantity of phosphorus to indicate a conversion of as much as 50 per cent of the injected protein into cellular protein.

In view of the evidence at hand, it seemed pertinent to set up a series of experiments which would put the current theories to further test, particularly with respect to the fate of the albumin in the depleted patient. Subjects were chosen who were in need of protein and who were not acutely ill, since it was thought that the utilization of albumin might be more efficient in such individuals. The amount of albumin administered was placed at a level well above the probable basic protein requirements. In order to assure the best possible opportunity for conversion, the caloric intake was kept at as high a level as the patient would tolerate. None of the diets were protein-free, but, except in one instance, the amount of diet protein was too low to maintain nitrogen balance.

II. PATIENT MATERIAL AND PROCEDURE

G. V. was a 21-year-old white male who had developed rheumatic heart disease with mitral stenosis and insufficiency at the age of five years. Cardiac decompensation had occurred on two occasions, during both of which there had been transient jaundice, perhaps secondary to chronic passive congestion of the liver. At the time of the present studies, the rheumatic disease

did not appear to be active, and the patient was compensated. He was, however, malnourished and appeared chronically ill. The basic diet provided 3300 calories and 2.6 Gms. of nitrogen. This was supplemented by the addition of 60 Gms. of beefsteak protein in two preliminary periods and subsequently by 60 Gms. of human albumin intravenously each day for a ten-day period.

E. G. was a 43-year-old white female who had been ill for ten months before the metabolic studies were begun. Her illness was characterized by migratory polyarthritides, irregular bouts of low-grade fever, transient accumulations of fluid in the pleural cavities, anorexia, and loss of weight. The diagnosis was never fully established in this patient, although it was believed that she had a generalized vascular disease, suggestive of periarteritis nodosa. At the time the metabolic observations were started, she was emaciated but afebrile, and appeared to be in a quiescent phase of her disease. She did not tolerate the type of low protein diet used in the other patients and a liquid formula providing 1200 calories and 8.2 Gms. of nitrogen was substituted in its place. Following a five-day control period, the intake was supplemented for 12 days by 60 Gms. daily of intravenous albumin.

W. R. was a 28-year-old female with a history of acute and chronic alcoholism. She was asymptomatic at the time of study and had no clinical evidence of liver disease. An inadequate diet associated with alcoholism had brought her weight below optimum. The basic diet in her case provided 4.2 Gms. of nitrogen and 2600 calories. Albumin was administered intravenously as in the other patients in the amount of 60 Gms. daily for 15 days.

Eugene G., a 26-year-old white male, presented the syndrome of neurocirculatory asthenia, but had no signs

of organic disease. There was a history of suboptimal calorie intake for more than a year but no recent loss of weight. He was physically the most normal subject of the group and probably had no significant protein depletion at the time of the experiment. His basal diet provided 2300 calories and 2.6 Gms. of nitrogen per diem.

A summary of the basic data on these patients plus the analytical values found on their control diets is presented in Table I. The albumin used was also analyzed and found to contain in each 100 cc. (a 25 per cent solution) 3.90 Gms. of nitrogen, 14 mg. of phosphorus, 13.84 m.eq. of sodium, and .78 m.eq. of chloride.

III. METHODS

All subjects were admitted to the special Metabolic Ward for study where well-controlled balances could be conducted. Diets were weighed and cooked under the supervision of the dietician, and any food refused by the patients was saved for analysis. The major emphasis was placed upon the determination of the balance of nitrogen, calcium and phosphorus. In addition the potassium balance was determined for W. R. and the sodium, potassium and chloride balances were determined for Eugene G. Urine was collected in periods of 24 hours. Stools were saved in five-day pools and separated by carmine markers. The intake for elements entering into the calculation of the balance was determined either by analysis of sample diets duplicating in all respects the food as served to the patients, or by the method of continuous sampling as described by Bassett and Van Alstine (14). The analytical procedures were carried out as follows: nitrogen in the urine, diet and stool by macro-Kjeldahl; calcium of the diet, urine and stool by the gravimetric procedure (15); daily analyses of the urinary phosphorus were made by the method of Fiske and Subbarow (16); phosphorus in the diet and feces by the gravimetric method (15); sodium and potassium were determined by the internal standard method of flame photometry (17); chloride by the open Carius method (18). Serum proteins were determined colorimetrically (19) and fractionated by Howe's method; they were also measured by a method based on the electrophoretic pattern (20). Urinary protein was determined by a modification of the biuret method (19). The dye T 1824 was used to estimate plasma volume using Gibson's technique (21). Hematoerits and erythrocyte sedimentation rates were done as described by Wintrobe (22).

IV. RESULTS

Nitrogen balance

The three subjects (G. V., W. R., and Eugene G.) who received a basic diet containing 4.0 Gms. or less of nitrogen a day were in negative nitrogen balance during the control periods, although from inspection of Figures 1, 3, 4 it is clear that they tended to approach equilibrium in the final preliminary days. E. G. (see Figure 2) who re-

ceived slightly more than 8 Gms. of food nitrogen of good quality each day, retained nitrogen for the first five days, in spite of the low caloric intake. In her case, the need for protein was obviously great and the reduction in calories apparently had not reached the critical level (1) where retention of nitrogen is impossible. All four patients were found to be in markedly positive nitrogen balance during the first few days of albumin injections and in none was there an appreciable increase in the urinary nitrogen during this time. This is in marked contrast to the prompt increase in urinary nitrogen in G. V. (Figure 1) when he was fed beefsteak protein in an amount equivalent to the albumin injected. After the first few days on albumin, the nitrogen

of the urine began to increase and rose slowly but progressively until the experimental period was terminated. In only one instance, however (the case of G. V.), did the urinary nitrogen become so great as to produce a negative nitrogen balance. The reason for this negative balance is undoubtedly to be found in the marked proteinuria which this man developed. When the injections of albumin were discontinued, the urinary nitrogen did not immediately decline to the level of pre-albumin days, but remained well above that level so that the negative balance of the five post-control days was in excess of that encountered in a preliminary period of equal length. This can hardly be interpreted other than as catabolism of some of the albumin still remaining in the body.

Proteinuria

All the patients excreted protein in the urine at some time during the course of administration of albumin, but in only one subject, G. V., was massive proteinuria encountered (see Figures 4). In his case distinct traces of albumin, although in amounts too minute for precise measurement, had appeared in the urine from time to time prior to parenteral albumin administration.

On the fourth day of the injections, however, there was a sharp rise in urinary protein which by the tenth day reached a maximum of 30 Gms. in 24 hours. This wastage of protein was undoubtedly responsible for the negative nitrogen balance at the end of the experimental period. The electrophoretic pattern of the urinary protein showed chiefly albumin with a trace of alpha globulin. The phenomenon of proteinuria was less marked in the remaining three patients, and its onset tended to be more delayed. At maximum E. G. excreted about 7 Gms. daily, Eugene G. 5 Gms. daily, while the amount excreted by W. R. did not rise above 3 Gms. in 24 hours. On cessation of injections of albumin, the proteinuria in these patients declined sharply or ceased altogether within five or six days.

Body weight

The two male patients (G. V. and Eugene G.) each gained about 2 kg. in weight during the time albumin was given, while the two women showed

Plasma protein and plasma volume

The rise in the concentration of plasma albumin above the control level was of the order of 2 Gms. per cent (Figures 5-8). The maximum concentration of albumin, 6.3 Gms. per cent, occurred in Eugene G. The concentration of globulin decreased as the albumin rose, but this was apparently an effect of dilution, since calculations of the total circulating globulin based on the increase in plasma volume showed no change. An expansion of the plasma volume to about 25 per cent above the initial values occurred in all cases but there was no change in the cell volume (except in the case of Eugene G. where rather large quantities of blood were removed for analysis). As a consequence the hematocrit fell. There was also a decrease in the erythrocyte sedimentation rate, presumably related to the higher concentration of plasma albumin.

EFFECT OF INTRAVENOUS ALBUMIN ON SERUM PROTEINS, BLOOD VOLUME, HEMATOCRIT AND ERYTHROCYTE SEDIMENTATION

GV AGE 21 MALE UNIT NO 182390

FIG. 5

gains of about 5 kg. (Figures 1-4). That the major factor in the weight gains of all patients was an expansion of the extracellular fluid volume, is suggested by the fact that the portion of albumin nitrogen apparently retained as protoplasm was quite inadequate to account for the weight gain in any patient. The mechanism of the large gain in extracellular fluid seen in the female patients was probably different in each case. Evidence to be brought out later suggests that albumin leaked into the extracellular fluid of E. G. where it tended to bind water. W. R., on the other hand, showed little evidence for the retention of large amounts of albumin in the extracellular fluid. She did, however, take large amounts of salt and water during this time and sodium retention was felt to be partially responsible for the accumulation of fluid. It will be noted (Figure 3) that some decrease in weight occurred before the injections of albumin were stopped, and that this coincided with a moderate restriction of the intake of salt and water.

Clinical course

In the categories already discussed, *i.e.*, nitrogen balance, proteinuria plasma proteins, plasma volume, hematocrit, and sedimentation rate, one notes a striking similarity in the reactions of the four patients. The sharply differing clinical responses, however, demonstrate the effect of the condition of the subject on the fate of the injected albumin.

Patient G. V. tolerated the injections of albumin well until the seventh day when he began to complain of loss of appetite and nausea. On the tenth day of albumin he was observed to be jaundiced. At no time was there any clear evidence of heart failure although he was known to have rheumatic heart disease and had had cardiac decompensation on two previous occasions. The jaundice and anorexia subsided promptly on cessation of the injections, and the remaining period of observation passed without incident. The intense proteinuria exhibited by this man may have acted as a safety valve to prevent expansion of his plasma volume to the point where it would have precipitated cardiac failure.

Patient E. G. ran a stormy clinical course. On the third day of albumin she became febrile and during the last few days of injections, as well as

FIG. 7

in the post-control period, there was remittent fever, with spikes as high as 40° C. A left peroneal palsy was observed on the fifth day, and on the sixth day edema became evident, which increased progressively throughout the rest of the experimental period. Small bilateral pleural effusions, which were present on admission, increased in size and a pericardial effusion was noted shortly after the patient returned to the general ward. Both the fever and the peripheral neuritis were felt to be part of her disease process. There seems little doubt, on the other hand, but that the edema, increasing pleural effusions, and the pericardial effusion were secondary to the administration of albumin. Obviously the remarkable gain of 5 kg. in weight in 12 days was due to the increasing anasarca.

Patient W. R. was unaffected by the injections until the eighth day. At this time she complained of a feeling of fullness in the abdomen and loss of appetite. During the evening of the 11th day, she had an attack of nocturnal paroxysmal dyspnea and rales were heard at the bases of both lungs. Restriction of salt was enforced beginning with the 12th day, following which there was a

prompt diuresis and a decrease in weight. Nevertheless, exertional dyspnea persisted and on occasion scattered rales were heard at the base of the right lung. Both symptoms and signs disappeared within two days after stopping the injections of albumin. It should be recalled that this patient had no evidence whatever of organic heart disease, and the syndrome of left ventricular failure appeared to be secondary to the increase in plasma volume, undoubtedly related to the intravenous administration of albumin.

Eugene G. received albumin intravenously for 15 days during periods 3 through 5 in the experiment. In period 4 the patient ran a low grade fever and had a mild diarrhea probably due to an intercurrent infection. During the last six days of the experimental period he too complained of a feeling of fullness in the abdomen, became anorexic, and vomited occasionally. It was difficult to evaluate his symptoms because of his exaggerated emotional responses and it was considered

improbable that albumin therapy was the chief basis of his discomfort. The objective effects were the gain in weight and the proteinuria which have been considered previously. Neither of these was of a magnitude to cause concern.

Calcium and phosphorus balances

Phosphorus balances were done on all patients primarily to estimate the amount of nitrogen which was released or bound in the catabolism or anabolism of tissue protein. This can be done only when the exchange of phosphorus with calcium is taken into consideration (23) and for this reason calcium balances were also carried out. The essential data are plotted in Figures 9-12.

CALCIUM AND PHOSPHORUS BALANCES

E.G. AGE 43 FEMALE UNIT NO. 267749

FIG. 10
For legend, see Figure 9.

Because of the dietary and other differences in the programs to which these patients were subjected, it will be necessary to include a brief description of each case.

The rheumatic patient, G. V., received an intake of phosphorus of 0.914 Gm. and calcium of 0.36 Gm. daily during the control periods. The phosphorus intake was increased appreciably when the beef supplement was given, but was not increased materially by albumin which contains very little phosphorus. The phosphorus balance followed the expected course during the control periods and at the time when beefsteak was given (*i.e.*, it correlated well with the nitrogen balance). In periods 6 and 7 when albumin was injected, one notes a gradual decrease in the excretion of uri-

nary phosphorus; and this continued throughout the post-control period (period 8). Because of the low intake of calcium, the balance was negative and the excretion in the urine very low. In periods 7 and 8, evidently as a consequence of the administration of albumin, calcium completely disappeared from the urine and its disappearance coincided with the lowest values of urinary phosphorus. An adequate diet was given in periods 9, 10, and 11 with retention of considerable nitrogen and phosphorus. Calcium was present again in the urine but the balance still remained slightly negative.

The calcium and phosphorus in the diet of E. G. were moderately high, 1.54 and 1.47 Gms. a day, respectively. Some of the irregularity in the intake (Figure 10) is the result of small losses through vomiting. Retention of both elements occurred in the control period. Injection of albumin did not produce much reduction in urinary phosphorus nor change in the phosphorus balance, a fact which constitutes the main argument in the

contention that this patient was unable to convert more than a small portion of the injected protein into cellular protoplasm. The calcium of the urine became less in the experimental period. In the post-control period its excretion almost ceased.

The basic diet of W. R., who was in nearly normal health, corresponded rather closely to that of G. V. and was low in nitrogen and calcium but adequate in phosphorus and calories (Table I). Figure 11 shows the pronounced decrease in the urinary phosphorus and the positive phosphorus balance during the last ten days on albumin. The irregularity of the curve of urinary phosphorus is probably due to the fact that she received five different diets during the experimental period each of which contained the same amount of nitrogen, but differed somewhat in its content of cal-

cium and phosphorus. As the method of continuous sampling was used for the analysis of her diets, the only analytical values obtained for intake were those for a five-day period. The negative calcium balance was not unexpected in view of the suboptimal intake of this element. It is to be noted that urinary calcium decreased in the post-albumin control period. We have then, in this patient, essentially a duplication of the results previously described in G. V.

On analysis of the diet of Eugene G., it was found to contain only 0.421 Gm. of phosphorus, which was less than had been anticipated. Since the experiment was already well under way when this was discovered, no supplementary phosphate was given. Calculations had shown the diet to be deficient in calcium, and the deficit in dietary calcium was made up by the administration of calcium gluconate in divided doses so that the daily intake was slightly in excess of 0.8 Gm. With the injection of albumin and in the post-control periods, urinary phosphorus decreased to very low levels. Fecal phosphorus, on the contrary, did not decrease. Because of the very low phosphorus intake, the balance was only slightly positive even at the time when the urinary excretion was minimal. The small rise in phosphorus excretion in period 4 coincides with an intercurrent infection when the patient was mildly febrile and had a few diarrheal stools. Although the intake of calcium should have been sufficient to maintain equilibrium, the balance was rather consistently negative. (This may have been due to the fact that the limited supply of available phosphorus was all used to meet the demand for conversion of albumin to cell protein, thus leaving little or no phosphorus to combine with the calcium.) However, the urinary calcium was affected as in the other patients and decreased in the second and third periods on albumin and in the post-albumin control period.

This consistent decrease in the urinary calcium is not without interest. Albright (13) has noted the association of decreased urinary calcium with intravenous administration of plasma protein. From the present studies, it seems to be of little importance in its effect on the overall calcium balance and correlates poorly with some of the other phenomena observed. It occurs whether or not there is a decrease in urinary phosphorus

(data on E. G.) and does not relate directly to the proteinuria. Serum calcium was followed carefully in only one patient (Eugene G.) and in this instance it rose from a control value of 11.3 mg. per cent to 14.9 mg. per cent, coincidentally with the peak value for the concentration of serum protein. This appears to be an indication that calcium was bound to the albumin retained in the blood stream. Nevertheless, from the quantitative point of view, our data suggest a far greater actual retention (decreased urinary excretion) of calcium than was required by the extra albumin in circulation. It is true, of course, that we are unable to give an accounting for the albumin which has diffused into the lymph or extracellular fluid and which might be expected to bind calcium. That some of the injected albumin may be reconstituted in the form of calcifiable osteoid tissue is likewise a possibility (13).

Actual versus "theoretical" nitrogen balance

In the metabolism of protoplasm the exchanges of nitrogen must in the long run be associated

with exchanges of phosphorus and potassium in amounts comparable to the proportion which exists in tissue, if normal structural relationships are to be maintained. The essential correctness of this thesis has been repeatedly demonstrated by Albright *et al.* (23-25) and constitutes the basis for the computation of the theoretical nitrogen balance. If one corrects the phosphorus balance for the amount combined with calcium, the remainder should give an index of the amount of nitrogen required in the anabolism and catabolism of tissue. In practice, during metabolic experiments, the actual nitrogen balance and the theoretical nitrogen balance are in fairly good agreement during the oral feeding of protein and in fasting.

In the preparations of Figures 13-16, both the actual and theoretical nitrogen balances have been plotted, not as deviations from control periods, but as they actually occurred. This makes very little difference except in the case of Eugene G., where the balance of phosphorus in preliminary periods was consistently and significantly negative.

ACTUAL AND THEORETICAL NITROGEN BALANCE

FIG. 13

The actual nitrogen balance is represented by the lined columns, the theoretical nitrogen balance by the clear columns. When overlapping occurs, the borders of the theoretical nitrogen balance columns are demarcated by squares superimposed on the limiting lines.

ACTUAL AND THEORETICAL NITROGEN BALANCE

EG AGE 43 FEMALE UNIT NO 267749

FIG. 14

For legend, see Figure 13.

In G. V. the actual and theoretical balances of nitrogen agreed fairly well until albumin was given. During these two periods the theoretical balance was at first much less positive than the actual balance, and in the post-albumin period it remained strongly positive although the actual balance had become negative (Figure 13).

The actual nitrogen balance of E. G. was markedly positive throughout the administration of albumin, but the theoretical balance was small and did not increase in the stepwise fashion observed in the other patients (Figure 14), a circumstance which will receive further comment presently.

The data on W. R. (Figure 15) are quite similar to those on G. V. and show a progressive increase in the "theoretical" retention of nitrogen during the 15 days on albumin. The theoretical balance differs from G. V., however, in that it did not continue to be strongly positive in the post-albumin period.

The general trend of events in subject Eugene G. (Figure 16) was similar to that in G. V. and W. R., but one notes that the theoretical nitrogen balance is only slightly positive during albumin injections when computed from phosphorus accruing to the body. On the other hand, when calculated from the deviation of the phosphorus balance from that of the preliminary control periods, the theoretical balance of nitrogen is almost as great as in the other two patients. We have commented previously on the almost complete disappearance of phosphorus from the urine of this man as the administration of albumin was continued. This suggests that the phosphorus derived from endogenous sources, instead of being excreted as in the control period, was being reutilized. It is to be noted further that his intake of phosphorus was low and that there may have been an obligatory excretion of phosphorus in the feces, for the latter did not decrease even when the demand for phosphorus seems to have been marked. Thus, the whole trend of his response may have been altered by the limited quantity of available phosphorus.

The fate of the injected protein

We have used the "theoretical" nitrogen balance, as has Albright (13, 23), to estimate the conversion of phosphorus-poor albumin into cel-

lular protein associated with the average amount of phosphorus. The fraction of the injected albumin which has been catabolized (deaminated) may be estimated from the rise in the excretion of the urinary nitrogen above the baseline of the control periods. The fraction of the unchanged albumin wasted by excretion in the urine can readily be measured also. With this information at hand, a balance sheet can be drawn up which shows in a general way what has happened to the albumin at any moment in the experiment. The injected albumin can be roughly accounted for as follows:

- (a) Albumin catabolized.
- (b) Albumin converted to tissue protein.

- (c) Albumin remaining in the blood stream, extracellular fluid, etc.
 (d) Albumin excreted in the urine.

There are obvious limitations to these calculations. For example, one cannot tell whether albumin is converted to tissue protein and then catabolized, or whether it is directly degraded, nor can one follow the fate of the carbon residues of the deaminated protein. The exact location of albumin apparently retained as such in the body is not known except for that part remaining in the plasma.

In setting up the balances two main assumptions were made: (1) that the exchange of nitro-

gen, phosphorus and calcium as measured on the final days of the control period would have remained constant throughout the experiment, had albumin not been administered; (2) deviations from the baseline of the control period could be ascribed to the albumin injections. Figure 17 has been constructed to illustrate the principles involved. The data are those obtained on G. V. The basic intake of nitrogen failed to meet the endogenous requirement of this patient, and he was in slightly negative balance during the foreperiod. When albumin was given, there was an increase in the urinary nitrogen above the basic excretion of the foreperiod. This represents albumin deaminated (burned). The gross retention of albumin in the body is the difference between that injected and that deaminated. The albumin retained is, therefore, greater than the actual positive nitrogen balance by this method of computation.

The cumulative burning of albumin in comparison with the amount converted to tissue protein in the case of G. V. has been graphed in Figure 18. One notes that neither process occurs to a significant degree until the third day of albumin injections. Thereafter both processes increased in stepwise fashion and continued even during the post-control period. The cumulative reten-

tion and conversion of albumin for this patient is depicted in Figure 19. There are two main points of interest, the delay in the conversion of

the retained albumin, and the apparent conversion of more albumin than was retained at the end of the control period. There are perhaps two possible explanations for the latter anomalous situation: (1) an error in the calcium-phosphorus balance which made the retention of the phosphorus appear greater than it actually was; (2) utilization of a small amount of the phosphorus for some other purpose than the conversion of albumin to tissue protein.

and conversion of albumin, respectively, by E. G. should be contrasted with those of G. V. In E. G. deamination proceeded in somewhat the same fashion, but to a greater degree and the amount of albumin converted to cell protein was very small. Even at the end of the post-control period, a large percentage of it remained unchanged in the body. Figures 22 and 23 show the same processes in patient W. R. The deamination began slowly, while conversion was somewhat more rapid and did not appear to continue beyond the fifth post-control day. Figures 24 and 25 prepared from the data on Eugene G. are similar. Evidence of conversion could no longer be obtained after the seventh post-albumin day. The catabolism occurred more slowly, and the urinary nitrogen was still above the pre-albumin level ten days after the injections were discontinued. About 50 per cent of the injected protein was incorporated into cell protein if one computes this fraction from the deviation of the phosphorus balance from the initial control periods.

The amount of albumin retained in the plasma of the individual patients at different times is presented in Table II. Inasmuch as these values are admittedly rough estimates, no definite con-

Note: Many of the calculations of plasma volume were made from changes in the hematocrit alone, according to the formula $PV_2 = PV_1 \frac{(H_1)(100 - H_2)}{(100 - H_1)(H_2)}$. Because of the known inaccuracies of venous hematocrit determinations, these figures are assumed to be rough estimates.

clusions will be drawn. However, it was our impression that the albumin seemed to leave the blood stream most rapidly in G. V. who had the smallest dose and the most pronounced proteinuria and least rapidly in E. G. who utilized it poorly. In no instance were observations continued long enough for all the extra albumin to have disappeared.

A summary of the fate of the albumin administered to these patients is given in Table III. The large excretion of urinary protein in G. V. and the comparatively small conversion of albu-

TABLE III

min to tissue protein in E. G. are emphasized again. W. R. and Eugene G., who were essentially normal, reacted to the injections with remarkable similarity.

V. DISCUSSION

The clinical response to human serum albumin given intravenously depends not only on its nutritive properties as a protein, but also on two other factors, namely, its potent osmotic activity and its nativity to the human body. Probably because of the last-named factor it is metabolized comparatively slowly under normal circumstances. Therefore, when the substance is given in large quantities, its slow utilization results in the accumulation of significant amounts of osmotically active protein. Thus to predict the response of the individual to injections of human albumin, one should take into consideration (a) his state of nutrition, especially with respect to protein, (b) the permeability of the capillaries in general and of the glomerulus in particular, and (c) the status of the cardiac reserve. Once an individual is saturated with albumin the compensatory adjustments may break down and proteinuria, cardiac decompensation, or edema may occur. Each of our four patients reacted differently to similar daily doses of intravenous albumin, and the importance of pre-existing disease (E. G.), renal permeability to protein (G. V.), dietary intake (E. G. and Eugene G.) and cardiac reserve (W. R.) are clearly shown.

The nutritive response as determined by the nitrogen balance deserves some comment even though this has been well described by other authors (12, 26). A positive nitrogen balance was present in all our patients at all times during the administration of albumin with the one exception of G. V. at a time when proteinuria was excessive. This exception should perhaps be emphasized since it is perfectly clear that the escape of albumin in the urine may reverse the nitrogen balance at a time when the need for protein still exists and the patient is still capable of storing considerable amounts of nitrogen. Moreover, the significance of the positive nitrogen balance should be determined in the light of the following facts. There is abundant evidence that plasma proteins will pass certain membranous barriers (27, 28). Albumin given intravenously

escapes through the capillary walls into the lymphatic spaces and to a smaller extent into the interstitial spaces. The accumulation of the whole protein in plasma, lymph, and the interstitial fluid has been described by Riegel (26) as a metabolic dead space and this is true in the sense that the nitrogen retained in the acute experiment has not all been converted into cellular protein. Thus under only one condition could the positive nitrogen balance be used as an indication of the nutritive value of this protein; namely, when an accurate calculation of the unchanged albumin in the body is at all times available. The amount retained in the plasma can be determined comparatively easily by plasma volume and serum protein determinations, but the quantity held outside the plasma would require measurement of the concentration of the albumin in the extracellular fluid as well as the volume of the latter. Indirect calculations of the unchanged albumin from data such as ours are perhaps possible but can be done only if other balances (calcium, phosphorus and potassium) are carried out.

The mode, extent and determining factors of utilization of parenterally administered plasma protein has been of considerable interest both to us and to other investigators. If one accepts the hypothesis that retention of phosphorus with albumin is a sign that the latter is being converted to cell protein, it seems certain that many patients will be able to effect such a modification. Three of our four patients showed evidence of conversion. The failure of our fourth patient, E. G., certain postoperative patients (26), and one normal patient who was receiving only 37.5 Gms. of protein a day (29) to show evidence of significant utilization may be taken as evidence that albumin is subject to the general laws of protein metabolism in the body.

The efficacy of albumin in relation to food protein was studied in only one patient, G. V. Beef protein orally and albumin intravenously were compared in quantities containing nearly equal amounts of nitrogen. The total conversion of albumin to cell protein by our method of estimation was 46 per cent, that for beef protein 22 per cent. It is obvious that no conclusions can be drawn from a single trial of this nature.

The actual mode of utilization of parenteral plasma protein has been discussed by several groups of workers. Whipple and his associates (28) have postulated "fluid interchange between the reserve stores and organ cells in which the protein is produced, modified and utilized in the body economy." Such a give and take might be accomplished without breaking the protein into its constituent amino acids. An alternate explanation is offered by Eckhardt (12) who suggests that the process is one of gradual decay, and that only as the protein is split into its individual components does it become available to the cells. According to this hypothesis albumin introduced into the blood stream would be broken down slowly by proteolytic enzymes and those constituents not of immediate use for re-synthesis of protein would be deaminated and excreted. By observing the rate at which injected albumin disappeared from the plasma, he was able to fit his data to a standard decay curve with a 50 per cent disappearance time in five days. Justification for neglecting the albumin held in extracellular fluid and lymph is based on the assumption that the proteins in these systems are in equilibrium with the plasma, although not necessarily of equal concentration. Thus when one measures the disappearance from the blood, one also measures the rate of disappearance from the extravascular spaces.

We were unable to establish similar decay curves in our patients because of too infrequent determinations of plasma volume. Decay in the sense used by Eckhardt would in our patients include albumin burned and converted, if one neglects the albumin lost in the urine. We have computed decay in our subjects using a time of five days for 50 per cent disappearance. Specifically this means that we have assumed that by the end of a five-day period, 50 per cent of the injected albumin would no longer be present as such in the body, but would have been either degraded or converted to cell protein. The values obtained for decay are compared with the sum of burning and conversion in Table IV and are expressed cumulatively as grams of nitrogen. The formula used for computing decay is that given for a series of daily injections (12). One sees fair correlation in the three patients, G. V., W. R., and Eugene G. This positive correlation we be-

TABLE IV.
Calculated decay of albumin vs sum of albumin catabolized and converted

Subject	G. V.		E. G.		W. R.		Eugene G.

25 days					130	126	130	121

* Values in this column refer to the per cent of decay that had taken place by the 5th, 10th, 15th day, etc.

† Values in this column refer to the sum of catabolism plus conversion also expressed as per cent of the amount of albumin received by the patient up to and including the 5th, 10th, and 15th days respectively.

lieve adds further support to the use of the theoretical nitrogen balance as a means of determining the conversion of albumin to some other form of protein. It is also clear that the rate at which a standard dose of albumin is metabolized is closely similar in these three individuals.

The poor correlation in E. G. is in agreement with our other data which indicate that a considerable fraction of the injected albumin remained as such presumably in edema fluid. Partial confirmation of this is found in the fact that the protein concentration of the pleural fluid was 6.2 Gms. per cent. It seems reasonable that excessive quantities of albumin leaked into the interstitial fluid in this patient, possibly because of increased capillary permeability. However, it does not seem likely that stagnation of the protein in the extracellular spaces was purely on a mechanical basis for if conversion of the albumin to cell protein and hence its removal from interstitial fluid depends upon contact with cells bordering on extravascular spaces, there should have been no lack of opportunity for this to occur. One must not overlook a possible influence of diet which was perhaps critically low in calories (Section I). The synthesis of protein in the cells may have been nearly maximal before the albumin was given, and further increase was prevented by a lack of source of energy.

The mechanism of the proteinuria, which eventually occurred in all our patients, requires brief comment. In no case was there suspicion of serious renal damage, since values for glomerular filtration rate and renal plasma flow were within normal range. This does not, however, rule out

the possibility of abnormal glomerular permeability, especially in G. V. who had traces of protein in his urine prior to albumin injections. It might be argued (a) that injections of albumin damage the glomeruli and that leakage of protein is permitted. A previously damaged glomerulus would perhaps leak more protein than one which was formerly normal. (b) That the normal glomerulus permits the passage of small amounts of protein which is ordinarily recaptured by the tubular cells and that proteinuria after albumin is secondary to the high concentration of albumin in the plasma and is due to filtration of more albumin than can be reabsorbed by the tubular cells. In view of the recent observations of Monk and Yuile (30), Terry *et al.* (31), and Rather (32) and the arguments advanced by them, the second mechanism appears to fit the facts better than the theory of damage. As was the case in animal experiments (31), the albuminuria of our patients ceased soon after the injections were stopped and tests of kidney function showed no decrease as a result of the procedure.

VI. SUMMARY

Each of four subjects received a daily dose of 60 Gms. of concentrated sodium-free albumin for ten or more days. Balances of nitrogen, calcium, phosphorus, and potassium were made during control, albumin, and post-albumin periods. Concomitant observations of serum protein fractions, plasma volume and renal function were made.

The individual variations in response are noted, namely (1) the development of an intense proteinuria in a patient convalescent from rheumatic

fever, without evidence of impaired renal function; (2) the retention of water with peripheral edema, hydrothorax and pericardial effusion, and the poor utilization of the injected protein in a woman with probable generalized vascular disease; (3) the excellent utilization, but eventual development of signs of cardio-respiratory embarrassment in a young woman in fair health except for moderate undernutrition; and (4) the modification of the response in a normal young male by other dietary factors. The mechanisms of these reactions are discussed.

It is felt that proteinuria will develop eventually in any patient when saturation with albumin has occurred and that this is probably not due to renal damage, but represents a physiological response when the maximum reabsorptive capacity of the renal tubules for protein is exceeded.

ACKNOWLEDGMENT

The authors express their appreciation to Dr. Lawrence A. Kohn, Department of Medicine, University of Rochester, for the determinations of plasma and blood volumes, and to Dr. Eric L. Alling, Department of Pathology, University of Rochester, for analysis of the serum proteins by electrophoresis.

CONGENITAL METHEMOGLOBINEMIA. A CLINICAL AND BIOCHEMICAL STUDY OF A CASE¹

By HOWARD A. EDER,² CLEMENT FINCH, AND RALPH W. McKEE

(From the Departments of Medicine and Biological Chemistry, Harvard Medical School, and the Medical Clinic, Peter Bent Brigham Hospital, Boston)

(Received for publication February 20, 1948)

Congenital methemoglobinemia is an unusual condition in which a large amount of intracellular hemoglobin exists as methemoglobin—pigment in which the hemoglobin iron is in the ferric state and incapable of carrying oxygen. The congenital type of methemoglobinemia is present from birth and is characterized by the constancy of the level of methemoglobin, by the relatively mild associated symptoms, and by polycythemia with no evidence of excessive blood destruction. There are 15 verified cases of congenital methemoglobinemia in the literature (1–10) and 10 additional cases of idiopathic methemoglobinemia (11–15) in which definite information as to the congenital aspect was lacking. In all of these cases the abnormal pigment was identified spectroscopically.

The subject of this study was a young man who presented the typical clinical picture of congenital methemoglobinemia. We have now followed him for five years—sufficient time to evaluate different forms of therapy for this condition.

CASE HISTORY

F. S., a 23-year-old public accountant, was admitted in December 1942 because of persistent cyanosis. He was born a "blue baby" and had been continually cyanotic with no noticeable fluctuation of degree of cyanosis during all his life. He could not indulge in strenuous exercise because of dyspnea, easy fatigability and pounding temporal headaches. He took no drugs and had no gastro-intestinal symptoms and there was no family history of similar cyanosis.

Physical examination disclosed a well-developed young man, 5 feet 11 inches tall and weighing 207 pounds. His skin had a slate blue color which was especially apparent in his lips, ears and finger nail beds. His conjunctivae were congested and the veins in the optic fundi were dark and dilated. There were no abnormalities on examination of his heart and lungs. Blood pressure was

130/90. He had no clubbing of his fingers, and his spleen and liver were not palpable.

Laboratory data: Hinton test for syphilis was negative; RBC was 6.5 million per mm.³; hematocrit was 58 per cent; Hb was 19 gms. per 100 cc.; WBC was 7,850 per mm.³ with a normal differential count; reticulocytes were 2.2 per cent. Hypotonic saline fragility was normal. Bone marrow puncture showed only a normoblastic hyperplasia, consistent with his polycythemia. Urine and stool examinations were negative. Plasma proteins were 7.8 gms. per 100 cc. with 4.4 gms. of albumin; serum bilirubin was 0.5 mgm. per 100 cc. Venous pressure was 100 cm. of water; circulation time was 14 sec. (decholin); vital capacity was 4 liters. Bromsulfalein excretion test showed a retention of 5 per cent of the dye in the serum in 30 min. EKG was normal; BMR was -15 and -12 per cent. X-ray of the chest showed normal lung fields with a heart of normal size and shape. X-ray of the large bowel showed no abnormalities. Spectroscopic examination of the blood showed the absorption bands characteristic of methemoglobin. By difference between total pigment and oxygen capacity it was estimated that 45 per cent of the total blood pigment was in the form of methemoglobin. Subsequent determinations of methemoglobin were done by the colorimetric method of Evelyn and Malloy (16). This method was checked by the carbon monoxide capacity method of Van Slyke and Hiller (17) and found to be accurate to ± 0.2 gm. in our hands.

After a control period of one week in which the level of methemoglobin remained constant he was given 90 mgm. of methylene blue intravenously. In 10 minutes half of the methemoglobin disappeared and by 30 minutes over 95 per cent had disappeared. He was then able to exercise vigorously without headaches and breathlessness which had previously so limited his activity. During the course of the following five years he was treated with ascorbic acid and with methylene blue by mouth. It was found that 240 mgm. of methylene blue in enteric coated tablets per day were well tolerated and were sufficient to keep him free of cyanosis. Coincident with this treatment polycythemia and reticulocytosis subsided. No toxic effects from this long-sustained treatment have been observed.

The identity of the abnormal pigment in this case was established spectroscopically as methemoglobin. There was a well-defined absorption band at 630μ which disappeared after addition

FIG. 1. OXYGEN DISSOCIATION CURVE OF PATIENT WITH 30 PER CENT METHEMOGLOBIN SUPERIMPOSED ON NORMAL OXYGEN DISSOCIATION CURVE

This is compared with the curve of Darling and Roughton on blood also containing about 30 per cent methemoglobin.

of sodium cyanide or of sodium hydrosulfite ($\text{Na}_2\text{S}_2\text{O}_4$) *in vitro*, or after injection of methylene blue *in vivo*.

Symptoms present in our patient and in others reported were those of anoxia due to the decreased oxygen-carrying capacity of the blood. In addition to this, Darling and Roughton (18) have recently described an additional adverse effect of the presence of methemoglobin on oxygen transport; this is a shift to the left of the oxygen dissociation curve as also occurs in carbon monoxide poisoning. This change hinders the transfer of oxygen from the blood to tissue.

The oxygen dissociation curve on the blood of our patient when his methemoglobin level was 30 per cent was determined by us and by the Harvard Fatigue Laboratory (Figure 1). In both cases the points fell on the normal curve and showed none of the changes described by Darling and Roughton. In four other cases in which oxygen dissociation curves were made, one (12) showed no shift while three showed definite shifts of the curve (1, 14, 19).

STUDIES OF THE MECHANISM

I. Site of the defect

To ascertain whether the factor responsible for the high methemoglobin content of the erythro-

FIG. 2. RATE OF METHEMOGLOBIN FORMATION IN PATIENT F. S. AFTER CESSATION OF METHYLENE BLUE THERAPY

FIG. 3. BEHAVIOR OF BLOOD FROM PATIENT F. S. AFTER TRANSFUSION INTO A PATIENT WITH REFRACTORY ANEMIA

cytes was in the cells or the plasma the patient's red cells were incubated with compatible normal serum, and normal cells were incubated with the patient's serum. At the end of 24 hours in the former the methemoglobin was not significantly reduced, and in the latter methemoglobin was not produced. This confirmed previous *in vitro* observations that there was no plasma factor of importance (2, 10).

To ascertain whether there was any factor in the body, outside the red cells, that influenced methemoglobin formation in the cells, the following *in vivo* experiment was performed. The methemoglobin in the patient's circulation was changed to normal hemoglobin by methylene blue administration, and the subsequent rate of methemoglobin formation in the patient was observed for 13 days (Figure 2). There was an average daily transformation of 3 per cent of the total hemoglobin into methemoglobin. At a time when methylene blue therapy had changed the patient's methemoglobin nearly all to normal hemoglobin he was bled and 225 cc. of his erythrocytes were infused into a patient with refractory anemia (Figure 3). This subject was chosen as a recipient because there would be no new hemoglobin formation to complicate the experiment. The volume of cells infused was calculated to be exactly equal to the volume of the recipient's own

circulating erythrocytes, as estimated from determination of her plasma volume (T-1824 method) and her hematocrit. After the infusion the rate of methemoglobin formation per day was 1.5 per cent of the total hemoglobin. It therefore appeared that the infused cells were forming methemoglobin in the recipient at the same rate at which they formed it in the donor. This result makes it appear improbable that there were any abnormal factors outside the red cells of the methemoglobinemic patient that influenced the formation of methemoglobin.

II. Failure of methemoglobin reduction

A solution of hemoglobin obtained by laking human red cells when exposed to an atmosphere of 95 per cent air and 5 per cent carbon dioxide will be completely converted to methemoglobin in about five days (Figure 4). This was equally true of hemoglobin from normal human subjects and of hemoglobin from our patient. Intact red cells possess a mechanism which prevents this from occurring and maintains the hemoglobin iron in the ferrous state. When we incubated normal cells in the rocker perfusion apparatus (20) no methemoglobin was formed as long as glucose was present in the media (Figure 4). When sodium nitrite was added to normal cells under these conditions methemoglobin was formed and then

FIG. 4. METHEMOGLOBIN LEVELS AFTER *IN VITRO* INCUBATION OF HEMOLYZED CELLS AND INTACT CELLS IN THE ROCKER PERFUSION APPARATUS

The *in vitro* effect of sodium nitrite on normal cells is also shown.

completely reduced within 12 hours. When cells from our patient containing methemoglobin were incubated in the apparatus there was no reduction and the methemoglobin level rose to about 30 per cent. This inability of the patient's cells to reduce methemoglobin corroborates previous *in vitro* observations (2, 6, 10).

Studies of the *in vivo* reduction rates of methemoglobin were performed by injecting, intravenously, 0.5 gm. of sodium nitrite into normal individuals and into the patient. Nitrite was chosen because it rapidly produced methemoglobin and was itself entirely gone from the blood stream by 60–90 minutes (21). In both the normal subject and the patient the sodium nitrite caused formation of about 2.5 gms. of methemoglobin per 100 cc. of blood within 40 minutes. On the other hand, after three hours, half of the methemoglobin formed had disappeared in the normal subject while in the patient the methemoglobin level showed no tendency to fall even after seven hours (Figure 5). This indicates that the normal mechanism for methemoglobin reduction fails to operate in this patient.

III. The methemoglobin reduction mechanism of the erythrocyte

In vitro studies of methemoglobin reduction in the red cell have shown that this is an enzymatic process in which glucose and lactate act as hydrogen donors (22–24). In view of this relationship, the carbohydrate metabolism of our patient's erythrocytes was investigated. The resting oxygen consumption measured in the Warburg manometric apparatus of 2 ml. of the patient's cells

FIG. 5. EFFECT OF 0.5 GM. SODIUM NITRITE ON PATIENT F. S. AND ON A NORMAL SUBJECT

TABLE I

Chemical survey of factors involved in carbohydrate metabolism in patient's blood

	Glucose utilization	Lactate utilization	Whole blood inorganic P	RBC				
				15 min. hydrolysable P	Acid soluble P	Total P	Resting O ₂ consumption	Flavine adenine dinucleotide
	mgm. per cent per hour	mgm. per cent per hour	mgm. per cent	mgm. per cent	mgm. per cent	mgm. per cent	mm. ³ per hour per 2 cc. of cells	gamma per cent
Normal average range	10-20(28)	0-5	2.4-3.5(29)	8.1-10.5(30)	50-60(27)	47-114(29)	10-30	35

was 22 mm.³ in 30 minutes as compared with 19 mm.³ in the normal control. Glycolysis as measured by glucose utilization (25) and lactate formation was normal. There was no lactate utilization. Flavine adenine dinucleotide in red cells was measured by the method of Ball *et al.* (26) using the enzyme system of d-amino acid oxidase with d, l-alanine as substrate.³ The amount of enzyme present was the same as in a normal control. Values for the 15 minute hydrolysable P of which the chief component is adenosine triphosphate were well within the normal range. Acid soluble P values comprising largely glycerol phosphate (27) were normal. Measurement of the other P partitions also showed nothing which indicated any abnormality of phosphorylation. These findings are summarized in Table I. To the extent of these studies we were unable to find any defect in the carbohydrate metabolism of the erythrocyte.

IV. Action of methylene blue

Harrop and Barron in 1928 (31) demonstrated that the addition of methylene blue caused a ten-fold increase in the oxygen consumption of mammalian red blood cells. Such an increase occurred to the same degree in our patient's erythrocytes as in the normal erythrocytes. This increase does not occur when the cells are washed free of glucose. When blood from the patient with congenital methemoglobinemia was treated with methylene blue in the presence of 100 mgm. per cent glucose there was complete reversion of the methemoglobin present to active hemoglobin. This

reversion was inhibited by M/300 iodoacetate.

The beneficial therapeutic effect of methylene blue has been observed clinically for 15 years in secondary types of methemoglobinemia (32-34) and has been recently reported in congenital methemoglobinemia (8, 14). The marked therapeutic effect of methylene blue in our patient suggests that it replaces some constituent of normal cells that is necessary for the enzymatic reduction of methemoglobin and that this is lacking in the cells of our patient.

V. Other oxidizing and reducing substances

Since hydrogen peroxide is formed in certain enzymatic reactions and then is decomposed by intracellular catalase, it seemed possible that a deficiency of catalase could be responsible for the presence of methemoglobin. Accordingly the catalase content of the patient's erythrocytes was determined by a modification of the methods of Morgulis and Juszat (35, 36) using 0.1 M hydrogen peroxide in 0.02 M phosphate buffer (pH 7.0) in a Warburg vessel. A normal catalase content of the red cells was found.

There are also substances present in blood cells and plasma that are capable of reducing methemoglobin. Ascorbic acid and glutathione are two such substances. This patient had blood levels of ascorbic acid averaging about 0.25 mgm. per cent compared to normal values of 1.5 to 2.0 mgm. per cent (37) despite adequate dietary ascorbic acid. The reduced glutathione level of the patient's whole blood was 20 mgm. per cent as compared to normal values of 40 mgm. per cent (38). One might consider that these substances represent a secondary line of defense of the body should the cell reconversion mechanism not func-

³ The standard flavine adenine dinucleotide and the d-amino acid oxidase was generously furnished by Dr. E. G. Ball.

tion. Certain circumstantial evidence indicates that this might be true. When hemoglobin or methemoglobin is injected intravenously in a dog an equilibrium point is reached at a methemoglobin concentration of 30 to 40 per cent of the total pigment (39, 40). By coincidence the 11 cases of congenital methemoglobinemia in which the per cent methemoglobin was reported showed the same equilibrium concentration.

When 2 gms. of ascorbic acid were given intravenously the methemoglobin level dropped from 25 to 15 per cent in ten hours. On doses of 300 to 500 mgm. of ascorbic acid per day for two weeks it was possible to lower the level of methemoglobin to 8–10 per cent of the total pigment. The sluggishness of this reaction and the fact that d-ascorbic acid which is physiologically inert is equally as effective as the naturally occurring isomer suggest that the effect of ascorbic acid is due to its direct reducing action on methemoglobin (41, 42) rather than to restoration of the normal enzymatic reduction mechanism.

DISCUSSION

Studies on this case have emphasized the normal mechanism by which the organism is able to maintain the hemoglobin-methemoglobin equilibrium within the red cell at about 99.6 per cent in favor of the ferrous form which is essential for transport of oxygen (43). There is undoubtedly steady formation of methemoglobin in the red cell, but the cells are capable of reducing the methemoglobin as soon as it is formed. In congenital methemoglobinemia we have shown that this mechanism fails to function, and it is pertinent to look further into the nature of this mechanism.

In 1930 Warburg (22) showed that methemoglobin formed in intact red cells could be reduced by the cells when glucose was added. This reduction of methemoglobin was accompanied by the disappearance of the glucose and the appearance of pyruvic acid. This effect could be inhibited by iodoacetate. Gibson (44) has recently shown that methemoglobin reduction can occur in the presence of fluoride, but there is accumulation of phosphoglycerate. These findings indicate that the reduction of methemoglobin is coupled with

glycolysis. In the glycolytic process diphosphopyridine nucleotide (coenzyme I) is reduced and is available for reduction of methemoglobin. (Red cells also contain triphosphopyridine nucleotide [coenzyme II] which becomes reduced by the direct oxidation of glucose through phosphogluconic acid.) Gutmann (45) has shown that reduced pyridine nucleotide will slowly reduce methemoglobin directly and this reaction can be accelerated by the addition of methylene blue. In normal cells it is likely that a flavoprotein which is present acts, as in other tissues, as a carrier between the pyridine nucleotide and the iron porphyrin. Little is known about the nature and properties of the flavoprotein in the red cell. Studies of Gibson have shown that in abnormal cells of his patients with congenital methemoglobinemia there is no defect in that part of the cycle concerned with formation of reduced pyridine nucleotide. Since glycolysis was shown to take place normally in the cells of our patient it is probable that reduced pyridine nucleotide is also formed normally in his cells. Since methylene blue has such a pronounced effect on reducing the methemoglobin in his cells it seems likely that the defect lies in these substances which catalyze the reduction of methemoglobin by reduced pyridine nucleotide. Gibson concluded that this defect in his patients was a deficiency of the flavoprotein, the coenzyme factor. In heart muscle this factor has been shown to be a flavine adenine dinucleotide (46). We analyzed for this substance using the d-amino acid oxidase as a test system and found it to be present in normal amounts in the cells of our patient. It is still a possibility that in his red cells this factor which is deficient is the flavine mononucleotide in which case the deficiency would not have been apparent by our method of analysis. It is also possible as both Kiese (47) and Gibson point out that the methylene blue does not function in a system already functioning actively (the coenzyme I system) but rather enters into a secondary sluggish system (the coenzyme II system) and converts it into a rapidly active system. Further studies are necessary to find out what flavoproteins are present in the red cell and whether they have the capacity to reduce methemoglobin directly or require other as yet unknown factors.

SUMMARY

A case of congenital methemoglobinemia was studied which demonstrated the following characteristics:

1. The level of methemoglobin was approximately 40 per cent of the total pigment and remained constant from day to day.

2. In the untreated patient there was a compensatory polycythemia and no evidence of excessive blood destruction. Alteration of the O₂ dissociation curve was not present.

3. Methylene blue and ascorbic acid were effective therapeutic agents.

4. The cause of the methemoglobinemia was shown to be the absence of a factor in the erythrocyte mechanism that in normal red cells rapidly reduces methemoglobin.

ACKNOWLEDGMENT

We should like to express our gratitude to Mr. Francis Stanley, the patient, without whose interest and cooperation these studies would have been impossible, and to Miss Katherine Hubbel for technical assistance.

THE EFFECTS OF INDUCED MALARIA, ACUTE STARVATION AND SEMI-STARVATION ON THE ELECTROPHORETIC DIAGRAM OF THE SERUM PROTEINS OF NORMAL YOUNG MEN¹

By HENRY LONGSTREET TAYLOR, OLAF MICKELSEN, AND ANCEL KEYS

(From the Laboratory of Physiological Hygiene, University of Minnesota, Minneapolis)

(Received for publication September 15, 1948)

During the last ten years, the technique for the electrophoretic analysis of serum proteins, originally described by Tiselius (1), has been standardized and a large number of important conditions have been studied. Luetscher (2) has reviewed this work and pointed out that the common denominator of all disease processes studied has been a relative decrease in the albumin fraction. Both acute and chronic infections produce an increase in the alpha globulin fraction which is often accompanied by an increase in the gamma globulin fraction. Chronic noninfectious processes such as ulcer or cancer also are accompanied by an increase in one or both of the alpha globulin fractions. Chow (3) has demonstrated that there exists a negative correlation between the relative amounts of serum albumin and the combined alpha globulins in disease states such as tuberculosis, ulcer and malnutrition. It has been shown that the characteristic response to protein depletion in the dog (4, 5) is also a decrease in albumin and an increase in the alpha globulins. Since this same change occurs in disease Chow has quite properly raised the question as to whether it is a response to the disease state or whether it is the result of the protein depletion which is common to these diseases.

¹ The work reported here was supported in part by The Brethren Service Committee, Elgin, Illinois; The Service Committee of The Society of Friends, Philadelphia; The Mennonites Central Committee, Akron, Pennsylvania; The John and Mary R. Markle Foundation, New York; The Sugar Research Foundation, New York; The National Dairy Council, operating on behalf of The American Dairy Association, Chicago; and The Home Missions Board of the Unitarian Society, Boston. In addition, support was provided under the terms of a contract, recommended by The Committee on Medical Research, between The Regents of the University of Minnesota and the Office of Scientific Research and Development. During the last phases of the work on semi-starvation, this contract was transferred to the Office of the Surgeon General, U. S. Army.

Experiments in this laboratory on the effects of induced malaria, of acute starvation and of semi-starvation on human volunteers provided an opportunity to study these questions in controlled and uncomplicated situations. Data from these experiments which throw some light on the relationship of protein depletion to serum protein composition during disease and starvation form the basis for this report.

CONDITIONS AND MATERIALS

All the subjects were males between the ages of 18 and 34 years and were members of Civilian Public Service. A careful medical examination failed to disclose signs of disease or abnormality when the men were admitted to the laboratory dormitory.

Eleven of these men took part in a long-term dietary experiment in which caloric and thiamine intake were carefully controlled. These diets were adequate in all known dietary constituents. This group of men was subjected at different times to both the stress of malarial fever and five days when they received no food. Ample time was allowed between the starvation stress and the induction of malaria for the subjects to recover completely from the effects of going without food.

These volunteers were inoculated with the McCoy strain of tertian malaria and all of them developed the active disease. After five to eight paroxysms and an average of 193 degree-hours of body temperature above 101° F., the malarial fever was terminated with quinine sulfate. Further details of this work will be presented elsewhere (6). Blood was drawn with the men in the fasting state the day before inoculation and again at the end of the febrile period. Plasma volumes were determined on the same day using the blue dye, T 1824. The concentration of the dye was determined by extrapolation of values obtained at 20, 30 and 40 minutes after the injection of the dye. The plasma volumes were calculated according to the procedure of Gibson and Evans (7).

Four of the 11 men were also subjected to five days of simultaneous starvation and hard work. The regimen of activity was so designed that the men expended 4,500 Calories a day during the fast. During this period the men lost an average of 13.8 pounds or 9 per cent of the initial body weight. Similar experiments which lasted for a shorter period of time have been described previously (8). Blood samples were drawn the morning of

the first day of fasting and at the end of the fifth day just before food was taken.

Another group of six men was studied during a six-month period of semi-starvation and at intervals during 32 weeks of recovery. Three additional starvation subjects were studied during the first 12 weeks of recovery. The diet consumed during the period of semi-starvation was an European type of famine diet which averaged 1,654 Calories per day and contained 59 grams of protein; the general plan of the experiment has been presented elsewhere (9) and a few special aspects have been described (10, 11). The six months of restricted diet resulted in a 24 per cent loss of body weight and the development of the typical signs and symptoms of starvation, *i.e.*, fatigue, weakness, depression, polyuria, bradycardia and edema. During refeeding the weight of the men reported here was regained slowly. After six weeks only 15 per cent of the lost weight had been regained. Corresponding weight gains and time intervals were 12 weeks, 40 per cent; 20 weeks, 104 per cent; and 32 weeks, 107 per cent. Plasma volumes were determined on some of these men during both the semi-starvation and recovery period using the blue dye technique. The details have been presented elsewhere (10).

The electrophoresis was carried out in the Tiselius apparatus according to the technique described by Longsworth (12). A 90 mm. center section cell was employed to give good resolution of the pattern. Samples of sera were diluted with veronal buffer with an ionic strength and pH of 0.1 and 8.6, respectively. This mixture was dialyzed against the buffer in the cold (4° C.) for two days and then placed in the electrophoresis cell. The concentration of the serum protein at this time was between 2.5 and 3 grams per 100 ml. of solution. The patterns were analyzed by measuring the area under each peak with a planimeter after the area for each peak had been designated by the method of Tiselius and Kabat (13). The areas of the various components were measured on both the ascending and descending patterns and these were then averaged. Serum protein concentrations were determined by the micro-Kjeldahl procedure of Keys

(14) and the concentrations of the various electrophoretic components were calculated assuming a constant refractive index and nitrogen factor for all fractions, an assumption which does not lead to large errors in normal serum (15).

RESULTS

The effects of malaria

The effect of malaria on the distribution of the electrophoretic components of the serum proteins of the 11 subjects is summarized in Table I. It will be noted that there was no essential change in the concentration of total protein. There was

TABLE II

FIG. 1. THE RELATIONSHIP BETWEEN THE ALBUMIN EXPRESSED AS PER CENT OF TOTAL ELECTROPHORETIC PATTERN AND THE SUM OF THE α_1 AND α_2 GLOBULINS EXPRESSED IN THE SAME UNITS

Data are taken from the analysis of the sera of 11 men before and after a bout of malaria.

also no change in the circulating serum volumes of this group which averaged $3,383 \pm 287$ cc. before inoculation with *plasmodium vivax* and $3,365$ cc. ± 307 cc. after the last paroxysm. There was a 12 per cent reduction in the relative amount of albumin which represents an actual decrease in concentration and a loss of circulating albumin.

The relative areas of the α_1 and α_2 fractions were averaged and plotted against that of albumin. The results are presented in Figure 1. The product-moment correlation is 0.72, a figure

which is regarded by Snedecor as a significant correlation.

The extent of the changes in the electrophoretic pattern was compared with the number of degree-hours of fever above 101° F. The data are presented in Table II. The alpha globulin appears to be the only component which showed a change related to the number of degree-hours of fever above 101° F. The product-moment correlation is 0.54 between degree-hours and the percentage change of α_1 globulin.

The analysis is presented for the control period, after 12 and 24 weeks of semi-starvation and after six, 12 and 32 weeks of rehabilitation.

The effects of acute starvation

The results of acute starvation are presented in Table III. There was a small but definite increase in the albumin fraction. This was accompanied by a decrease in both of the alpha globulins. The total protein concentration was increased by 14 per cent, a consequence presumably of the mild acidosis which accompanied the fast.

The effects of semi-starvation

Complete data are available on two men during the period of semi-starvation and recovery. This is presented in Table IV. There was an increase in the albumin fraction after 12 weeks of semi-starvation when these men had lost 18 per cent of their original body weight. The relative amount of albumin dropped somewhat after 24 weeks of semi-starvation when it was slightly above the value for the control period. During early rehabilitation it increased again slightly and then returned to normal by the end of 20 weeks when the original body weight had been recovered. There was a small decrease in the gamma globulin which was apparent at 12 weeks of semi-starvation and showed no further change after 24 weeks. It should be noted, however, that the gamma globulin had not reached control levels at the end of 32 weeks of recovery. The changes in the globulins of intermediate mobility do not appear to be significant except for the elevation of the beta fraction above the control levels at the end of recovery.

It had been planned to study six men throughout the course of the experiment but four samples of serum drawn at the end of semi-starvation were lost in an unfortunate refrigeration accident. The available data on these six men are presented in Table V. The results are similar and confirmatory to those found in Table IV.

Since the plasma volume tends to increase during starvation (10), the calculation of the total circulating protein clarifies the interpretation of the electrophoretic pattern. Plasma volumes were available for subjects 122 and 123 at the beginning and end of the semi-starvation pe-

TABLE V

Results from the same six men are averaged for control, after 12 weeks of semi-starvation (S12) and after six and 12 weeks of rehabilitation (R6 and R12). Values for four men are averaged for the periods R20 and R34 (after 20 and 34 weeks of rehabilitation). For normal comparison, mean values and their standard deviations are given for 30 normal men. Values are in grams per 100 cc. for total serum proteins and as per cent of total proteins represented by the several fractions.

TABLE VI

The plasma volumes (in cubic centimeters) and the circulating fractions of the serum proteins (in grams) of two men before (C) and after 24 weeks of semi-starvation (S24)

Subject Number	Period	Plasma Vol.	Circulating Protein Fractions					Gamma

riod. The circulating protein fractions in grams are presented in Table VI along with data for 17 normal young men. It will be noted that the only consistent changes were an increase in the beta globulin and a small decrease in the gamma fraction. The total circulating serum protein fractions for four men in the control period and after 12 weeks of semi-starvation are presented in Table VII. A definite increase in the albumin fraction and a small decrease in the circulating α_1 and gamma globulins are shown in this table.

Plasma volumes and electrophoretic analyses of sera were available on three additional men during the 12 weeks of recovery. These data are presented in Table VIII to illustrate the situation in early recovery. By R6 these men, who were in the group fed a "good" rehabilitation diet, had regained 20 per cent and at R12 they had recovered 53 per cent of the weight lost during semi-starvation. It will be noted that the decrease in the albumin fraction between R6 and R12 is due entirely to the data obtained from one man and

that no change occurred in the total circulating gamma globulin.

DISCUSSION

The effects of malaria on the electrophoretic pattern confirm the negative correlation between the relative concentration of albumin and that of the alpha globulins reported by Chow (3). Malaria can no longer be regarded as an exception to the rule that acute infectious disease is accompanied by an increase in the alpha globulins.

It may be noted that when the total amounts of the various fractions in the circulation are calculated from the plasma volumes, albumin appears to be lost from the circulation and that there are definite additions to some of the globulin fractions. The effect of malaria on the electrophoretic pattern appears to differ from some other diseases such as scarlet fever (16) and rheumatic fever (16) in that no increase in the α_2 globulin accompanied the α_1 rise. Dole (17) has shown that attacks of relapsing malaria do not produce the increase in α_1 globulin reported here. The absence of this response in the malaria patient who has had several bouts with the disease might appear to be an adaptation to recurring stress.

Guttman *et al.* (18) studied the effects of malarial fever in syphilitic patients. These investigators used a phosphate buffer at pH 7.4 which does not separate α_1 globulin from the albumin fraction and this fact presumably accounts for

their failure to find any changes in the alpha globulins.

The decrease in albumin and the increase in alpha globulins which have been observed in many acute infectious diseases are not explicable as a result of a simple negative nitrogen balance such as is produced by a caloric deficit. The changes noted during malaria here are similar to those seen in pneumonia (19), scarlet fever (16), rheumatic fever (16), and tonsillitis (20). In contrast, no such changes were seen in acute starvation in spite of the fact that the subjects in the latter experiments lost roughly 50 grams of nitrogen each. This protein loss is comparable to that reported for some acute infectious diseases, including pneumonia and malaria (21, 22).

We have noted that, in our studies on malaria, there was little or no relation between the changes in albumin concentration and the number of hours of fever above 101° F. This is in contrast to reports, based on salting out with sodium sulfate, that the depression of the albumin concentration is related to the intensity of the malarial fever in both men (23) and monkeys (24). The difference may be related to the severity and duration of the disease; the malaria here was relatively mild and of short duration. However, our data indicate that the change in α_1 globulin is a more sensitive index to the severity of the disease than is the change in albumin content.

The results of the Minnesota semi-starvation

experiment clearly demonstrate that protein depletion due to simple caloric undernutrition does not explain the decreased relative albumin and increased alpha globulins shown in the electrophoretic patterns of sera from patients suffering from chronic debilitating diseases such as tuberculosis (25), ulcer (3), cancer (25) and rheumatoid arthritis (26). There can be no question that the subjects of the Minnesota starvation experiment were badly depleted of tissue protein. Corrections of the body weight loss (to be discussed elsewhere [27]) for changes in fat by the specific gravity method, for changes in extracellular water by the NASCN method and for changes in bone salt by X-ray density techniques indicate that the body weight loss underestimated the loss of active tissue, *i.e.*, more than 24 per cent of the original protein-containing tissues of the body were lost by these men.

It is apparent, then, that the alterations in the electrophoretic pattern of the serum proteins in the acute and chronic diseases mentioned above are not the results of protein depletion produced simply by a negative caloric balance. The question may be raised as to whether the "toxic destruction" of body protein can account for the picture in these diseases. The so-called catabolic phase (28) is defined empirically as a negative nitrogen balance which will not respond to an additional intake of calories or protein.

At the present time, the evidence is insufficient to decide whether the catabolic phase of protein metabolism is causally related to the characteristic alterations in the patterns seen in various diseases. Several facts suggest that the pattern changes are independent of this type of nitrogen loss. The negative nitrogen balance in tuberculosis, a disease which produces the alterations in pattern described above, is easily corrected by an increased intake of calories and protein (29). In addition, Peters (28) has presented evidence that the serum albumins, determined by the sodium sulfate technique, may increase in infectious diseases in spite of a markedly negative nitrogen balance. Finally, the same author states that after surgery the albumin concentration may decrease before the negative nitrogen balance becomes apparent.

The possibility cannot be ignored that the relatively decreased albumin and increased alpha

globulins observed in many diseases is a response to a certain type of injury and is independent of nitrogen loss over a wide range. It should be clearly understood that we are not denying that extreme protein depletion, *i.e.*, protein depletion resulting in more than 24 per cent weight loss, may result in decreased relative albumin concentration which may or may not be accompanied by a relative increase in the alpha globulin.

It is frequently stated that protein depletion results in a lowered resistance to infection (30). It is of interest, therefore, that the protein depletion produced in the Minnesota experiment resulted in only minimal reduction of circulating gamma globulins. While there is much evidence to indicate that the majority of circulating antibodies are found in the gamma globulin fraction (31), it has not been shown that gamma globulin is made up entirely of antibodies. Therefore, the small losses observed in semi-starvation in man do not necessarily represent depletion of circulating antibodies.

SUMMARY AND CONCLUSIONS

1. The sera of 12 normal young men were examined by the moving boundary method of electrophoresis before and after a bout of induced malaria. The malarial fever was allowed to run through five to eight paroxysms and an average of 193 hours over 101° F.

2. Changes in a given electrophoretic fraction after malaria were of the same order of magnitude regardless of whether they were expressed as per cent of total pattern, grams per 100 cc. of solution or as total circulating proteins. The albumin fraction decreased 14.5 per cent while the α_1 , beta and gamma globulins increased 62, 20 and 19 per cent, respectively.

3. The extent of the change in the α_1 globulin fraction after malaria more closely paralleled the number of degree-hours of fever over 101° F. than did the changes in any other fraction of the serum proteins.

4. Four men underwent acute starvation with hard work for five days which resulted in a 9 per cent loss of body weight. Electrophoretic analysis of the sera of these men before and after acute starvation demonstrated no important change other than a general increase in concentration due to a mild dehydration.

5. Nine subjects took part in a semi-starvation experiment which produced a 24 per cent loss of weight in the course of six months and the classical symptoms of famine, *i.e.*, weakness, fatigue, depression, bradycardia, polyuria and edema. The sera of two of these men were examined in the electrophoresis apparatus six times before and throughout both semi-starvation and recovery. The sera of the other seven men were examined at less frequent intervals. It was possible to calculate circulating plasma protein fractions for a number of these men.

6. The serum albumin fraction showed definite increases above normal after 12 weeks of semi-starvation and a loss of 18 per cent of the body weight. This was not accompanied by significant increases in other fractions. After 24 weeks of semi-starvation the albumin fraction had returned to normal. The albumin fraction was not depressed below normal at any time during the experiment.

7. Changes in the globulin fractions were minimal except for a definite increase in the beta fraction at the end of recovery when the men were a little overweight.

8. It is concluded that there are no changes in the electrophoretic diagram which are specifically characteristic of caloric undernutrition whether produced by complete starvation or semi-starvation.

9. At the present time, there is no valid evidence which relates the characteristic decrease in albumin and increase in the alpha globulins which are observed in many acute and chronic diseases to the protein deficiency of caloric undernutrition which may accompany these diseases.

ACKNOWLEDGMENT

This work was possible only with the whole-hearted co-operation of the volunteers from Civilian Public Service who served both as subjects and assistants, and all the regular personnel of the Laboratory. Special help in the operation of the electrophoresis apparatus was given by Glen Fisher. Drs. Samuel Wells, Rodney Kendall, Frederick Hoffbauer, Francis Lynch and Russell Wilder provided clinical advice and aid.

COMPLEMENT AND ITS COMPONENTS IN HUMAN CEREBROSPINAL FLUID¹

BY MICHAEL HEIDELBERGER AND ROBERT H. MULLER

(From the Department of Medicine, College of Physicians and Surgeons, Columbia University, and the Presbyterian Hospital, New York City)

(Received for publication August 5, 1948)

It has been stated that normal human cerebrospinal fluid (CSF) does not contain complement (1, 2). Complement (C') has been noted, however, in CSF from occasional cases of meningitis and its presence has even been used as an indication of the permeability of the meningeo-vascular barrier (Weil & Kafka, in Katzenelbogen [1]). It has also been claimed that the absence of C' activity in normal CSF was due to lack of midpiece (3).

Since these observations were made, more sensitive methods for the estimation of C' have become available. These are based upon the spectrophotometric measurement (4) of the 50 per cent hemolytic unit (C'_{H50}) in the presence of adequate amounts of Ca^{++} and Mg^{++} (5, 6). Improvements have also been made in the tests for the four recognized components of C' (7). The question of the presence or absence of C' in spinal fluid was therefore reexamined with the help of these methods.

Because rather large quantities of CSF were required, samples collected prior to the taking of pneumo-encephalograms were used.² Cases showing infections of the central nervous system were excluded; otherwise, few of the samples could be considered entirely normal CSF. The fluids are listed in the table in order of increasing total protein content, with the hospital discharge diagnoses of the patients. All samples were examined for red blood cells, and when unusual numbers of these were found the fluids were excluded, since any C' found might have been due to adventitious admixture with blood.

About one-third of the fluids showed C' activity when tested directly by addition of 4 or 5 ml. to 1.5 ml. of a suspension of sensitized sheep red cells and sufficient buffer to give a total volume of 7.5 ml. as described by

Mayer *et al.* (4-6). Samples showing less than 3 per cent lysis are listed as non-lytic since the optical densities in the spectrophotometer were roughly only double those of the blanks.

At this low level, however, the test for C' is extremely insensitive as the von Krogh equation relating the quantity of C' to hemolysis (4, 5) indicates that 0.5 of a 50 per cent hemolytic unit is required to give 3 per cent hemolysis. An indirect method of estimation of C' activity was therefore considered more appropriate, and the samples were also tested by addition of preferably several different volumes to an accurately estimated portion of diluted human serum C' approximating a 50 per cent hemolytic unit, 1.5 ml. of a suspension of sensitized red cells and sufficient buffer as above.

The quantity of human C' to be used may be determined as follows: A 1:50, 1:75, or 1:100 dilution of human serum, depending upon its C' activity, is made up in the saline-veronal buffer containing 0.0005 M $MgCl_2$ and 0.00015 M $CaCl_2$ as described by Mayer *et al.* (5). With the aid of calibrated pipettes, accurately measured 1.5, 2.0, and 2.5 ml. portions of the diluted serum are mixed into 50 ml. centrifuge tubes containing 1.5 ml. (5×10^8) sensitized sheep erythrocytes and the above buffer, to make a final volume of 7.5 ml. The tubes are capped and, after incubation in a water bath at 37° C. for 45 min., with occasional shaking, are centrifuged for 10 min. at 2000 r.p.m. The supernatants are decanted with care and the degree of hemolysis is estimated spectrophotometrically and the C'_{H50} calculated (4). The optimal amount of human C' to which to add the CSF is in the range 0.8 to 0.9 C'_{H50} , and in this range an increase of 0.03 C'_{H50} should be significant. The human C' , if sterile, may best be preserved in small sealed glass ampoules in a CO_2 box. Once it has been standardized, a fresh ampoule may be opened for each set of CSF, but blanks, in duplicate, containing the predetermined volume of C' dilution and the hemolytic system should always be run along with the tubes containing C' and CSF.

In all but two CSF samples tested with a fraction of a C'_{H50} of human C' , an increase in hemolysis was noted over that of the C' itself. The results of these experiments are given in Table I as the difference in 50 per cent hemolytic units (C'_{H50}) above that of the control human C' dilution alone. These values are not all directly comparable, since only nine samples were tested at different volumes and six with more than one fraction of a C'_{H50} . For example, CSF 21 was tested by addition of 1.0, 2.0, and 4.0 ml. to 0.8 C'_{H50} of human C' and

¹ The work reported in this communication was carried out in part under the Harkness Research Fund of the Presbyterian Hospital and in part under a grant from the Rockefeller Foundation.

² The authors wish to thank Dr. Elvin A. Kabat, Neurological Institute, New York City, and Dr. Hattie E. Alexander, Babies' Hospital, New York City, for the fluids.

* Analysés by the laboratories of the Neurological Institute and the Babies' Hospital. Values in parentheses were carried out on another sample taken within one week.

† 5.0 ml. CSF used. 1.0 ml. of CSF 5 increased the activity of human C' by 0.1 C'_{H50}; 1.0 ml. of CSF 6 gave an increase of 0.03 C'_{H50}; 1.0 ml. of CSF 7 gave no measurable increase. The value of 0.02 C'_{H50} for CSF 1 is considered significant only in connection with the positive direct test.

‡ The second value was obtained after storage in the CO₂ box for 5.5 months in a rubber-capped bottle. The sample absorbed much CO₂ and the acidity was neutralized with 0.1 N and N NaOH before the tests were run. Identical values were obtained with 2.5 and with 4.0 ml. of the sample, indicating an anticomplementary effect for the larger amount. This occurred whether the additions were made to 0.6 or to 1.2 C'_{H50} of human C'.

§ After 4.5 months in the dry ice box.

|| After five months in the dry ice box.

¶ 3.0 ml. gave only 10% hemolysis, but this corresponds to 0.62 C'_{H50}, a value proportional to that for 4.0 ml., 0.78. Hence the sample had no anticomplementary effect in the larger amount.

** Although negative in its original state, a portion, dialyzed under negative pressure in the cold to one-fourth its volume in a period of five days, showed 7% lysis on the direct test with 4.0 ml. and 0.31 increase in C'_{H50} with 2.0 ml. on the indirect test, equivalent to 2% and 0.16 C'_{H50} on the original volume, with no allowance for deterioration. The initial indirect test showed 0.03 C'_{H50}.

†† With 0.84 C'_{H50} of human C', 1.0 ml. CSF 21 gave an increase of 0.15 C'_{H50}, 2.0 ml. an increase of 0.30. In another experiment with 1.27 C'_{H50}, 3.5 ml. gave an increase of only 0.20.

‡‡ Obtained with 3.0 ml. An increase of 0.33 C'_{H50} was given by 2.0 ml. This sample, also, was not anticomplementary in the quantities used. In this instance, also, there was little difference whether the test was carried out with 0.9 or with 1.3 C'_{H50}. It appears preferable, however, to add the CSF to somewhat less than 1 C'_{H50} of human C', since the lytic curve flattens out greatly above 1.3 units and the uncertainties of analysis are therefore greater.

showed a greater increase in lysis per milliliter of CSF the smaller the amount of CSF used. A 1.0 ml. portion of CSF 5 also showed a relatively greater increase in lysis than the 4.0 ml. sample, but this was not true of CSF 6. Similarly, CSF 13 caused a relatively greater increase at the 2.5 ml. level than at 4.0 ml., but CSF 14, 18, and 22 did not. It is therefore probable that the results given for some of the other CSF samples do not represent maximal values but reflect instead a balance between the activity of C' and the anticomplementary properties of the individual CSF.

Qualitative tests of C' components were also made in many instances, with reagents for C'1 and C'4 prepared from guinea pig serum according to Bier *et al.* (7). Tests for C'3 were made with a reagent obtained by incubation of 1.0 ml. of guinea pig serum with 0.4 ml. of a 1:1000 dilution of "Liquoid" in 0.85 per cent saline for 15 min. at 37° C. and dilution of the resulting mixture with saline to ten times the original serum volume.³ C'2 was tested for indirectly by noting any increased lysis of sensitized sheep red cells over that caused by a fraction of a unit of human C' in the presence of heat-inactivated guinea pig C' to provide adequate amounts of C'3 (*cf.* 7). The results are reported in the table as the highest degree of lysis from 0 to ++++ above that of the reagent controls. In tests for C'1, C'3, and C'4 the reagent controls showed no lysis but in two series of tests for C'2 the human C' plus inactivated guinea pig C' controls gave ++ and +++ hemolysis, respectively. In the table, therefore, + for C'2 represents an increase in lysis to +++ or +++++, respectively.

The tests for components indicated that all were present in varying amounts in human CSF without any obvious correlation between the strength of the test for a component and total protein content of the CSF. It is difficult to account for the failure of CSF 8, 12, 16, and 21 to show lysis in the direct test when all four components of C' could be shown to be present and when CSF 21, especially, gave such high values at different levels in the indirect test. Possibly, even though C'2, the limiting component of human complement (7), was present in these samples its amount may have been insufficient either to equal a measurable fraction of a C'_{H50} in 4 ml., the largest quantity used in the direct test, or to overcome the anticomplementary properties characteristic of this larger quantity and not present in 1 or 2 ml. Moreover, the tests for the components were carried out in a volume of 0.8 ml., so that the con-

ditions of these tests were very different from those for total hemolytic activity.

A surprising feature of the component tests was the weakness of many of those for C'4, a component usually present in very high titer in the C' of human serum (7). No attempt was made to titrate the level of C'4.

In some of the cases of this series, such as those with post-traumatic encephalopathies or with brain tumors with CSF in the high total protein range, the presence of C' might be accounted for by alterations in the permeability of the meningo-vascular barrier. There are, nevertheless, other CSF samples showing C' activity in which the total protein was within the normal range and the diagnosis indicated no disturbance which would be expected to alter the permeability of the barrier.

The principal outcome of the present studies, therefore, has been to demonstrate the presence of C' or its components in almost all of a series of 22 CSF samples, without obvious relation to the diagnoses of the cases from which the samples were taken or to the protein content of the fluids. Owing to the limitations of the tests themselves and the difficulties of their interpretation it would require study of a very large series of CSF samples before satisfactory answers could be given to questions relating the presence or absence of C' or its components in CSF to the physiology or pathology of the meningo-vascular barrier, or to the diagnosis of any particular disease. It is hoped that the positive findings, on the other hand, will serve to encourage a more detailed and lengthy study.

SUMMARY

1. About one-third of the samples of CSF taken prior to pneumo-encephalography showed hemolytic C' activity when tested directly with sensitized sheep red cells.
2. All but two of 22 samples tested increased lysis by a fractional unit of serum C'.
3. Qualitative tests for the four components of C' indicated their presence in those samples in which tests were made for all.
4. C' activity has been demonstrated in CSF containing protein in normal concentration and in CSF from patients with clinical diagnoses

³ Unpublished communication from Professor Graciela Leyton, Santiago, Chile.

compatible with a normal permeability of the meningo-vascular barrier.

ASSOCIATION ANNOUNCEMENT

The 41st annual meeting of the American Society for Clinical Investigation will be held at the Chalfonte-Haddon Hall, Atlantic City, N. J., on Monday, May 2, 1949, at 9 a.m.

For those who may be interested, the annual meeting of the American Association for Research in Psychosomatic Problems will be held at the same hotel on Saturday, April 30, at 9 a.m., and Sunday morning.

The annual meeting of the Association of American Physicians will be held on Tuesday and Wednesday, May 3 and 4, also at the Chalfonte-Haddon Hall.

HEMATOLOGIC OBSERVATIONS IN PATIENTS WITH CHRONIC HEPATIC INSUFFICIENCY STERNAL BONE MARROW MORPHOLOGY AND BONE MARROW PLASMACYTOSIS^{1, 2}

BY THOMAS JARROLD AND RICHARD W. VILTER

(From the Department of Internal Medicine, College of Medicine, University of Cincinnati, Cincinnati)

(Received for publication June 9, 1948)

Macrocytic anemia is found in many persons with chronic hepatic disease. The incidence recorded by different observers had varied from 18% to 89%. Observations reported by Wintrobe (1) set the incidence of macrocytosis at 40.9% in 44 persons with cirrhosis and 62.5% in eight persons with cirrhosis and malignant disease of the liver. However, the pathogenesis of the anemia has not been clearly defined. In 1933 Wintrobe and Shumacker (2) and in 1936 Wintrobe (1) suggested that the anemia was due to the inability of a chronically and extensively diseased liver to store the antipernicious anemia factor. This opinion was supported by Goldhamer, Isaacs and Sturgis (3) who found that the antianemic substance was either reduced or absent in the livers of persons with hepatic cirrhosis and macrocytic anemia. However, in 1938 Schiff, Rich, and Simon (4) recovered an antipernicious anemia substance from the livers of cirrhotics with macrocytic anemia; they inferred that the defect was one of utilization rather than storage of this factor.

Poor hematologic response to liver extract has been the rule (1, 5), although an occasional patient with portal cirrhosis will respond as dramatically as a person with pernicious anemia in relapse (2); some cases are said to have responded to folic acid (6). In spite of these inconsistencies, the prevailing hypothesis still classes the macrocytic anemia of chronic liver disease with the erythrocyte maturation factor deficiency anemias. This is true even though the only report on bone marrow morphology

failed to demonstrate megaloblastic maturation arrest (7). The data presented in this paper stress the normoblastic rather than megaloblastic type of bone marrow morphology found in the majority of patients with cirrhosis and macrocytic anemia. Thus any type of erythrocyte maturation factor defect becomes an unlikely etiologic possibility in these patients.] Observations are also presented which correlate bone marrow plasmacytosis with hyperglobulinemia in persons with cirrhosis and suggest a causal relationship.

MATERIAL AND METHODS

The subjects chosen for study were 30 consecutive patients with a primary diagnosis of portal cirrhosis uncomplicated by recent hemorrhage. The diagnosis was made by history, physical examination, and by laboratory tests of liver function. Each of these tests was done at least two times on each patient and included the bromsulfalein retention, thymol turbidity, thymol flocculation,³ cephalin-cholesterol flocculation,³ quantitative serum bilirubin,³ alkaline phosphatase,³ and prothrombin time. The amount of urobilinogen in the stool³ was determined in 11 cases. The serum albumin/globulin ratios were determined using a modified biuret method (8) and the Coleman Junior spectrophotometer. In 23 patients liver biopsies were done and the diagnosis was confirmed histologically.

The hematologic characteristics of each subject's peripheral blood were determined on two or more occasions. Reticulocyte counts were performed daily and erythrocyte and hemoglobin determinations were made every second day while the therapeutic effects of various agents were being investigated. Red and white blood cell counts were performed with pipettes and counting chambers certified by the U. S. Bureau of Standards. Hematocrit determinations were made on oxalated venous blood (4 mgm. of potassium oxalate and 6 mgm. ammonium oxalate per 5 cc. blood), centrifuged for 30 minutes in a Wintrobe tube at 3,000 r.p.m. Hemoglobin

¹ Presented in part before the American Society for Clinical Investigation, Atlantic City, N. J., May 3, 1948.

² This work has been supported by grants from the Robert Gould Research Foundation, Merck and Company, Inc., and the United States Public Health Service (RG 991). Lederle and Company supplied the Folic Acid.

³ These tests were performed by the Gastric Laboratory of the Cincinnati General Hospital and the authors wish to acknowledge the cooperation of Dr. Leon Schiff, director of the Gastric Laboratory.

was determined as oxyhemoglobin with the Coleman Junior spectrophotometer. Reticulocyte and platelet counts were made by the wet technique using Dameshek's method (9). The cytology of the bone marrow obtained by sternal aspiration was studied one or more times. Cover slip preparations for cytologic study of capillary blood and sternal marrow were stained by Wright-Giemsa stains.

The differential counts of the sternal marrow were done independently by each of the authors. Agreement was excellent in each instance, and the average of the two counts was taken as the representative value. In each case 500 non-erythroid nucleated cells were counted. The erythroid nucleated cells were expressed as numbers per 100 non-erythroid nucleated cells.

During the period of hospitalization each of the patients was placed on a "hepatic regime." This included a high protein, high carbohydrate, high vitamin diet supplemented with crystalline B-complex vitamins, protein hydrolysates, ferrous sulfate, and such lipotropic substances as choline and methionine. Several patients were given crude liver extract ("Intraheptol") intravenously. In addition each patient was given crude or refined liver extract intramuscularly or folic acid orally. The crude

liver extract was given in 5 cc. doses three times weekly and the refined liver in doses of 50 U.S.P. units three times each week. The folic acid was given in single oral doses of 100 mgm. daily. Patient No. 3 was kept on a vitamin B-poor diet and after ten days of observation with only an insignificant fall in erythrocytes was given one-half lb. of ground beef daily for three weeks. Thereafter this patient was treated in the manner described above.

RESULTS OF PERIPHERAL BLOOD STUDIES

Of the 30 persons studied, 24 were anemic, *i.e.*, they had less than 4,000,000 erythrocytes per cubic millimeter. Twenty of these had a macrocytic anemia (MCV of 96 cubic microns or above) and four had a normocytic anemia. The cells usually were normochromic. The remaining six patients were not anemic. Stained smears of the peripheral blood revealed moderate macrocytosis with minimal anisocytosis, poikilocytosis and polychromatophilia. Hypersegmented poly-

morphonuclear leucocytes were not observed. Reticulocytosis, usually ranging from 2% to 7.7% but in one instance as high as 13.5%, was found even though these patients did not show evidence of recent hemorrhage. The guaiac test for occult blood in the stool was faintly positive in several of these patients; but the degree of reticulocytosis was correlated with an increased bilirubinemia much more closely than with such minimal evidence of bleeding. The hematologic characteristics found in these 30 patients with portal cirrhosis are recorded in Table I.

RESULTS OF BONE MARROW STUDIES

The bone marrow appeared normally cellular in 21 subjects and moderately hypocellular in nine. The cytologic aspects and distribution of nucleated cells of the erythroid series usually were normal, although in 11 subjects there was mod-

erate hyperplasia at the normoblast level (see Table II). Such hyperplasia was found in the most anemic patients. In only three patients (Nos. 3, 5, and 14) was there a suggestion of the "megaloblastic maturation arrest" so characteristic of pernicious anemia and related macrocytic anemias. These patients were remarkable in that they were the only ones with signs of advanced multiple B-complex vitamin deficiencies, and each had a dietary history consistent with a prolonged deficiency of extrinsic factor. One of these patients (Case No. 5) had 57° free hydrochloric acid in the gastric secretions following histamine stimulation. The other two had none. Unfortunately there was no opportunity to repeat the test in the latter cases.

The granulocytic cells were normal; there were no bizarre metamyelocytes. The lymphocyte percentages were at the upper limits of normal.

There was, however, a striking and consistent increase in the number of plasmacytes. In the 30 patients the average was 10.5% with extremes of 2% to 23.5%. Normally, in our laboratory plasmacytes recorded as a percentage of nucleated nonerythroid cells range from 0 to 3.5% with an average of 1%. This plasmacyte hyperplasia was approximately proportional to the degree of hyperglobulinemia found in these patients. Table III and Figure 1 illustrate this relationship. In addition to the 30 patients with portal cirrhosis, we have studied the bone marrow of seven persons with biliary cirrhosis and seven with infectious hepatitis as revealed by liver biopsies. In

The cases are arranged in the order of increasing globulin values. Under these conditions there is a similar progressive increase in the percentage of plasma cells.

FIG. 1. GRAPHIC ILLUSTRATION OF DATA PRESENTED IN TABLE III

these 14 cases, unlike those with portal cirrhosis, plasmacytosis as high as 7% occurred only once and in none was there any correlation between the number of plasmacytes and the amount of serum globulin.

PROGRESS AND RESPONSE TO TREATMENT

There was no evidence of blood regeneration in the majority of patients on the hepatic regime supplemented with either liver extract or folic acid as previously described (see Figure 2). Slow non-specific hematologic improvement was observed in only five patients. This coincided with improvement in the patient's general condition.

A specific hematologic response similar to that which follows the administration of liver extract to persons with pernicious anemia was observed in only two patients (Nos. 3 and 14). A third patient (No. 5) who received one-half lb. of beef daily for 21 days in place of the hepatic regime, had an erythrocyte and hemoglobin rise of 2.75 to 3.72 millions and 10.3 to 12.2 grams respectively in this period of time. The reticulocytes did not increase during this period but were sustained between 4% and 5%, gradually falling toward the end of the period. The mean corpuscular volume fell from 120 to 108 cubic microns. Each of these three patients (Nos. 3, 5, and 14) had a significant number of megalos-

M.W., c.♀.36, PORTAL CIRRHOSIS, ALCOHOLIC

FIG. 2. THIS PATIENT HAD PROVED PORTAL CIRRHOSIS AND A MACROCYTIC ANEMIA

This graph illustrates the ineffectiveness of liver extract and folic acid in influencing the course of this anemia.

blasts and early erythroblasts in the bone marrow, but patients Nos. 3 and 14 were too ill to be subjected to the same experiment as patient No. 5. In fact patient No. 14 deteriorated rapidly even though there had been a hematologic response, and expired three weeks after hospital admission. Wintrobe (1) has recorded a similar experience.

DISCUSSION

The characteristics of the peripheral blood of the cirrhotic subjects in this study are comparable to those previously described (1, 5). Sixty-five per cent had macrocytic anemia; 15% had normocytic anemia and 20% no anemia. The accumulated evidence indicates that in the great majority of these subjects the macrocytic anemia of chronic liver disease occurred because of a metabolic defect other than erythrocyte maturation factor (liver factor) deficiency. The peripheral blood of persons with portal cirrhosis and macrocytic anemia did not reveal the anisocytosis, poikilocytosis, nucleated erythrocytes or multilobed poly-

morphonuclear leucocytes characteristic of pernicious anemia and related diseases. The bone marrow was normoblastic and either normally cellular or slightly hypocellular rather than hypercellular and megaloblastic. Finally, there was no change in the bone marrow or peripheral blood of persons with uncomplicated cirrhosis which could be credited to treatment with crude or refined liver extract or folic acid in large doses.

Three patients in this series had eaten diets for many years which were grossly deficient in B-complex vitamins, animal protein and presumably extrinsic factor. These were the only persons who exhibited advanced lesions of vitamin B-complex deficiency disease, such as glossitis, neuritis, and pellagrous dermatitis; these were the instances in which there were a significant number of megaloblasts or early erythroblasts in the bone marrow and in which there was a hematologic response to liver extract, and in one case, a response following the administration of ground beef. We believe that these three patients and the several similar patients reported in the medi-

cal literature (1, 10) are examples of extrinsic factor deficiency macrocytic anemia in persons with cirrhosis rather than the macrocytic anemia of chronic liver disease.

Several other points warrant brief comment. Blood loss cannot be invoked to explain the consistent initial reticulocytosis found in these patients and described previously by Rosenberg (5). Hemolysis or mild hypersplenism are unlikely causes because the level of urobilinogen in the stools was not elevated in any patient in whom the test was performed, and the bilirubin in the blood was usually of the direct reacting type. The uniform type of macrocytosis cannot be explained satisfactorily. Both of these problems require further investigation.

The bone marrow plasmacytosis in portal cirrhosis, which correlated roughly with the degree of hyperglobulinemia, has its counterpart in several other diseases and has been noted previously in European communications (11, 12). Such a correlation has also been found in lymphopathia venereum, Boeck's sarcoid, kala azar, multiple myeloma and serum sickness (13-17). As a result of studies on diseases associated with elevated serum globulin, Bing and Plum (18) conclude that the formation of globulin takes place in the plasmacyte. This opinion is supported by more recent investigations concerning the relationship of plasmacytosis to hyperimmune reactions and hyperglobulinemia (17-22). These studies indicate that plasmacytes develop in bone marrow and spleen in animals sensitized to bacterial or simple protein antigens as antibody globulin increases. Passively induced hyperglobulinemia or passive sensitization and shock do not induce a plasmacyte response.

Our studies do not indicate whether globulin is formed by plasmacytes or whether the plasmacytes appear in response to globulin formed elsewhere. Because of the studies cited above and by analogy with multiple myeloma it is likely that the plasmacyte is responsible for the excessive production of one of the beta or gamma globulins found by electrophoresis in the serum of patients with myeloma or portal cirrhosis (23). The stimulus to plasmacytosis in cirrhosis may be an antigen which the damaged liver either liberates or cannot inactivate.

Other globulins may be produced by lympho-

cytes and by the macrophages of the bone marrow, liver and other parts of the reticulo-endothelium without the mediation of the plasmacyte. Perhaps this is the reason why globulin may be elevated in acute hepatitis and biliary cirrhosis without a consistent increase in plasmacytes in bone marrow or other tissues.

CONCLUSIONS

1. A hematological survey has been carried out in 30 patients with proved portal cirrhosis.
2. Moderate or severe macrocytic anemia was present in 65% of the patients.
3. Reticulocytosis usually ranged up to 8% but in one instance was as high as 13.5%. It could not be explained by acute loss of blood.
4. The bone marrow of these persons was normally cellular or moderately hypocellular. In 11 there was moderate normoblastic hyperplasia. The only patients with megaloblastic maturation arrest had evidence of "extrinsic factor" deficiency.
5. Plasmacytes were consistently increased in the sternal bone marrows of these patients. The degree of plasmacytosis correlated roughly with the degree of hyperglobulinemia, suggesting a cause and effect relationship of a similar nature to that observed in multiple myeloma.
6. The macrocytic anemia failed to respond to liver extract and folic acid although there was an occasional spontaneous hematologic remission associated with a decrease in the severity of the cirrhosis. There was a significant hematologic response to liver extract or ground beef only in the three patients in whom extrinsic factor deficiency was suspected.
7. The normoblastic bone marrow and the lack of response to liver extract and folic acid in the majority of cases strongly suggests that the macrocytic anemia of chronic liver disease is produced by a metabolic defect entirely different from that responsible for pernicious and related macrocytic anemias.

ACKNOWLEDGMENTS

The authors wish to acknowledge the assistance of Miss Virginia R. Hawkins in performing the hematologic determinations of the peripheral blood and Mrs. Betty Fichter in carrying out the serum albumin-globulin determinations. We also wish to acknowledge the assistance

rendered by Dr. Robert Cogswell who performed the liver biopsies and to Dr. Daniel Richfield who examined the histologic specimens.

THE CARDIOVASCULAR EFFECTS OF ACUTELY INDUCED HYPOTHERMIA^{1,2}

By O. PREC,³ R. ROSENMAN, K. BRAUN,⁴ S. RODBARD, AND L. N. KATZ

(From the Cardiovascular Department,⁵ Medical Research Institute, Michael Reese Hospital, Chicago)

(Received for publication July 19, 1948)

Under the conditions of relatively constant body temperature which exist in warm blooded animals including man, the physiological variations occurring in circulatory functions such as blood pressure, cardiac output, and circulatory rate are small. This relative constancy has led to the development of the concept of circulatory homeostasis. In recent years there has been a growing appreciation that the warm blooded animal may survive at greatly reduced body temperature during which marked circulatory changes may occur. The interdependence of the several cardiovascular functions has indicated the need for a correlation of the circulatory adjustments which occur during such progressive hypothermia. Only in this manner would it be possible to interpret the significance of the changes and their respective roles in the integration of the animal under the stress imposed by the hypothermia. Such studies may also have value in the development of rational therapy for individuals who have undergone prolonged exposure to cold.

METHOD

Fifteen heparinized dogs were anesthetized with intravenously administered sodium pentobarbital. Three animals were used as controls and 12 were cooled. Nine of these latter were maintained in a lighter and three in a deeper plane of anesthesia. The results were compared with those of six other dogs, in a parallel study (1), subjected to hyperthermia.

Respiratory rate and oxygen consumption were recorded with a basal metabolism apparatus attached to a tracheal cannula. Kymographic tracings of arterial blood pressure were obtained from the femoral artery

with a mercury manometer. Pulse rates were obtained from electrocardiograms taken simultaneously with the other measurements.

Cardiac output was calculated from the oxygen consumption and the arteriovenous oxygen difference according to Fick's formula (2). Two radio-opaque cardiac catheters were introduced through the external jugular veins and, with the aid of fluoroscopy, the distal ends were placed in the right auricle and in the pulmonary artery, respectively. The proximal ends of the catheters were connected with saline manometers for the recording of mean pressures. The location of the catheters and their zero pressures were verified at post-mortem examination. To ensure maximal mixing of the blood returning to the heart, samples of venous blood were taken from the cannulated femoral artery. Arterial blood was obtained from the cannulated femoral artery. In the course of each experiment, 100 to 150 cc. of blood were withdrawn and replaced with isotonic saline solution. The Van Slyke-Neill technic (3) was used in the analysis of blood O₂ and CO₂. Hematocrits were determined by the Wintrobe method (4), arterial blood being employed.

Control measurements were made when the blood pressure and respiration of the animal became stabilized. The animals were then covered with chipped-ice packs. Body temperatures were recorded from thermometers placed deeply in the rectosigmoid area and protected from the ice packs. The mean cooling period was about two hours during which the body temperatures fell to 29° C. The animal was then dried, covered with thin sheets, and exposed to radiant heat. However, the body temperatures continued to fall to 27° C, before beginning to rise. The mean rewarming period lasted five to six hours, at the end of which body temperatures usually had returned to 37° C. Ten or 11 determinations were obtained in each experiment, measurements being taken after each 2 degree change of body temperature.

Evaluation of the method

Measurements of right auricular and pulmonary arterial pressures represent only the approximate mean values. The changes in pressure were considered to be of greater significance. During periods of extreme bradypnea resulting from severe respiratory center depression, great variations in concentration of blood gases occur during each respiratory cycle, and this produces errors in the direct Fick method. This inaccuracy is further increased by the fact that the usual means of collecting blood samples makes it impossible to obtain exactly

FIG. 1. COMPOSITE GRAPH OF DATA OBTAINED FROM THREE CONTROL DOGS, ANESTHETIZED BUT NOT SUBJECTED TO COOLING, DURING FOUR-HOUR PERIOD

Values for oxygen consumption and cardiac output are given in cc./kg./min. Respiratory and heart rates are in frequency per minute. The results in each individual dog are indicated by a different type of line.

simultaneously withdrawn arterial and mixed venous blood. These samples were drawn within 10 seconds of each other. This error is shown by the progressive accumulation of carbon dioxide in both arterial and venous bloods during apneic periods. Thus arterial blood taken at the end of apneic periods may contain more carbon dioxide than is found in venous blood withdrawn at the beginning of the respiratory cycle. For this reason, data obtained during marked bradypnea are not used in the conclusions of this study, although these are included in the tables.

Measurements similar to those described above were obtained over four-hour periods in a control group of three dogs, anesthetized but not subjected to cooling procedures (Figure 1).

The site from which true mixed venous blood can be obtained has been a controversial point, and has been discussed by many investigators in connection with the application of the direct Fick method in man. In the latter instance it has been demonstrated that there are only slight differences between blood taken from the right ventricle or pulmonary artery and that from the right auricle provided that the catheter tip is placed near

the tricuspid valve orifice. A different situation exists in dogs, our experience having shown that the oxygen content of blood taken from the right ventricle or pulmonary artery may differ markedly from that of the right auricle. We therefore adopted catheterization of the pulmonary artery as a more exact technic. Even greater errors may be introduced when venous blood is taken from the inferior vena cava due to the presence of more highly oxygenated renal venous blood which is poorly mixed with that from other viscera.

DISCUSSION OF RESULTS

Oxygen consumption

The initial values for oxygen consumption lay within a relatively small range, 4.0 to 6.6 cc./kg./min. In the control series no significant changes in oxygen consumption occurred during the four-hour period of observation (Figure 1). In eight cooled dogs there was a progressive decrease in oxygen consumption as body temperature fell. In two less deeply anesthetized animals the oxygen consumption increased from 4.7 to 10.8 and from 4.0 to 4.7 cc./kg./min. during shivering, and then suddenly decreased. In two other dogs the oxygen consumption did not vary significantly until body temperature fell to 31°C. Very little variation was noted in the pattern of change after the temperature fell below 31°C. The lowest oxygen consumption was 1.4 cc./kg./min. During rewarming periods there was a progressive increase in oxygen consumption in all instances. Data on three deeply anesthetized animals are given in Figure 2.

The direct relationship which was found between oxygen consumption and body temperature is similar to the results of other investigators in dogs (5). Variations in oxygen consumption up to 200% which we observed in the four less deeply anesthetized dogs mentioned above were associated with marked shivering and increase in pulse rate. There is general agreement that shivering causes an increase in oxygen consumption (6). Visible shivering occurred at temperatures as low as 29°C in our experiments and did not prevent further drop in body temperature. Figure 3 represents an experiment in which marked shivering did not prevent further fall in body temperature. It should be noted that the rate of temperature change during both the cooling and rewarming periods was not altered by marked shivering. The administration of 100% oxygen did not inhibit or delay the

FIG. 2. A COMPOSITE GRAPH OF AVERAGE DATA OBTAINED FROM THREE DEEPLY ANESTHETIZED ANIMALS DURING COOLING AND REWARMING

It should be noted that the cardiac output failed to increase during the rewarming period despite the acceleration of the heart rate. Values for oxygen consumption and cardiac output are given in cc./kg./min., pulse rate is in beats per minute.

onset of shivering although such effects have been reported by others (7).

Respiratory rate

In the control series there was very little change in the respiratory rate (Figure 1). During both cooling and rewarming a close correlation between the respiratory rate and body temperature was found. This direct relationship was seen in the three deeply anesthetized (Figure 2) and in most of the less deeply anesthetized dogs. In two instances transient increases in respiratory rate from 28 to 40/min. and from 6 to 15/min. occurred during the early cooling period. The initial rates varied from 6 to 28/min., and at the

lowest temperature varied from 0.5 to 7/min. except in one dog. In this animal the lowest rate was 22, this dog maintaining a high rate during the entire experiment. In almost every case, the lowest respiratory rate occurred at the lowest body temperature. Following rewarming the range of variation in the rates was greater than that prior to cooling. Similar results have been obtained by others in animals (4, 8).

Pulse rate

The direct relationship found between changes in body temperature and pulse rate is shown in Figure 2. During the induction of cooling, increases in pulse rate occurred in the two animals

FIG. 3. A COMPOSITE GRAPH SHOWING THE EFFECT OF SHIVERING IN ONE DOG

It should be noted that the curves obtained in this animal do not differ significantly from those obtained from dogs in which shivering was absent (Figure 2). Values of oxygen consumption and cardiac output are given in cc./kg./min.

in which the rates were measured immediately after the ice was applied, although there was visible shivering in only one dog. In both there were transient increases in pulse and respiratory rates and blood pressure. After these initial changes an almost linear relationship was found, the changes in pulse rate closely paralleling the changes in body temperature. The lowest pulse rate was 59/min. occurring at 27° C. In the control series very slight changes were noted (Figure 1).

Similar results have been described by others (6). The direct effect of cold on the sinus pacemaker appears to be responsible for the variations in heart rate. The absence of changes in the control series lends support to the assumption that the changes are not due to the anesthetic.

Electrocardiogram

Electrocardiograms (Lead II) were taken simultaneously with other measurements in 11 dogs. The progressive sinus bradycardia occurring during cooling has already been discussed. There were no marked abnormalities of the P waves but the P-R intervals increased progressively as the heart rate slowed. A gradual widening of the ventricular complexes occurred during cooling, being maximal at the lowest temperatures in all but one dog. The average duration of the QRS complex was 0.062 seconds prior to cooling and this was doubled at 27° C. At the lowest temperatures an intraventricular block with notched S wave was noted in all but one animal. Figure 4 illustrates the relationship between the body temperature and QRS duration. Electrical systole, calculated from Bazett's formula, (9), was progressively increased from a normal value for K of 0.33 to 0.43 at 29°C (Figure 4). An elevation of the S-T segment was observed in nine dogs and a depression in one dog. In two dogs the T wave reversed its direction and in four there was a decreased amplitude. No change in T wave was noted in four dogs. Ventricular premature beats were seen in three dogs and in two instances, ventricular fibrillation developed.

The initial effect of cooling is on the heart rate and on the duration of electrical systole. Change in contour and duration of ventricular complexes and S-T-T changes occur later. The effect of cooling on repolarization in the ventricles is seen

before the effect on depolarization. All these changes were entirely reversible during the re-warming phase. The observed abnormalities are probably a direct effect of cold on the metabolic processes in the myocardium, since similar changes occur with direct application of cold (10). A more severe hypothermia than we used has been reported to induce auricular fibrillation and A-V block (11), but we did not observe these effects.

Blood pressure

Sodium pentobarbital anesthesia induces a fall in blood pressure, apparently via a direct effect on the vasomotor center and this is often associated with a spontaneous fall in body temperature (12). In confirmation of this we noted in the control series a fall in temperature of as much as 2° C, associated with a decrease in mean blood pressure during the first two hours of anesthesia; after this, the pressure was maintained at the lower level in two dogs and returned to control values in the third (Figure 1).

A slight but transient rise in blood pressure usually occurred immediately after the application of the ice packs. Shivering usually elicited further increases as great as 25%, but in two dogs, despite shivering, mean blood pressures fell 6% and 17% respectively. The fall in blood pressure which occurred during the early phase was

FIG. 4. RELATIONSHIP OF BODY TEMPERATURE TO ELECTROCARDIOGRAPHIC CHANGES

Discussed in text.

TABLE I
Cardiac output (cc./kg./min.) changes during cooling and rewarming

‡ Extreme bradypnea. Estimation inaccurate.

not great in most instances and not markedly different from the changes observed in the control series. However, during prolonged cooling, there was a tendency to a progressive fall in blood pressure and at the lowest body temperature in the dogs that survived, mean pressures had fallen to as low as 54% of the original level (Figure 2). During rewarming there was a consistent rise in blood pressure, the latter returning almost to initial values when the body temperature returned to 37° C.

This laboratory has previously called attention to a relationship between body temperature and blood pressure which may be demonstrated in several species of animals. In these, lowering of the temperature is accompanied by a fall in blood pressure (13, 14). Certain data in the literature on the effect of cooling on the blood pressure of man (15), and animals (16) are in accord with this concept. However, other data (17) show that the blood pressure may be maintained at control levels in cooled anesthetized rats until the body temperature falls below 29° C. Proskauer *et al.* (18) found that in rats an initial decrease was followed after 30 minutes of cooling by a rise in blood pressure. These responses may be a part of the homeostatic mechanisms which maintain the body temperature at normal levels, and in the face of a falling temperature maintain the blood pressure for a period.

Cardiac output

Control values for cardiac output in these and other dogs that we have studied averaged 112 cc./kg./min. and varied from 60 to 175 (Table I).

In the deeply anesthetized dogs there was a marked decrease in output during cooling and a small increase during rewarming (Figure 2). The lowest outputs occurred, not at the lowest body temperatures, but during the early rewarming periods, and these ranged between 35% and 56% of the control values. There were greater variations in cardiac output in the six less deeply anesthetized dogs. In 10 of the 12 dogs, there was a definite increase in output as great as 126% during the first period of cooling. These changes were associated with shivering, increased oxygen consumption and pulse rate, or a combination of these factors. For example, dog C1, which shivered violently during early cooling, showed an increase of oxygen consumption from 64 to 146 cc./min., of respiratory rate from 28 to 40 and of pulse rate from 176 to 196. The sudden rise in output in dog C9 at 31° C was related to an acute fall in arterial oxygen content which persisted until sudden vasomotor collapse led to death. This sudden increase in output may have been due to the acute anoxia but the etiology of the sudden drop in arterial oxygen content could not be accounted for. Complete recovery from cooling was not achieved as can be seen from the fact that the final values for cardiac output during rewarming were only about 50% of the original values. Increases in output during rewarming of the less deeply anesthetized dogs were more rapid and of a higher order and almost returned to the original values.

In two dogs of the control group there was a fall in cardiac output coincident with a spontaneous fall in body temperature up to 2° C (Figure 1). The reduction in cardiac output may have been due

partly to an anesthetic action and partly to the reduction of body temperature. No change in either body temperature or cardiac output occurred in the third control dog.

Right auricular and pulmonary arterial pressures

The mean right auricular pressure was measured in 10 dogs during cooling and in three controls, and was found to lie in the range of ± 1 mm. Hg in the control state (compared to the atmospheric pressure). In the control group variations occurred, usually in a negative direction, the largest being -2 mm. Hg. In the animals which were cooled the changes were as great as -5 mm. Hg.

The mean pulmonary arterial pressure was measured in eight cooled and three control dogs. The initial values lay in a range of 7 to 12 mm. Hg except in one dog in which it was 15 mm. Hg. In both control and cooled dogs there were rapid and substantial variations in pressures as much as 6 mm. Hg. The pressure changes were not consistent and bore no relationship to pulse rate, blood pressure, stroke volume or cardiac output.

With the development of the direct Fick method in man, much attention has been paid to the right auricular pressure and its relation to cardiac output. McMichael and his group (19) have promulgated the idea that within physiological limits in the compensated heart, the cardiac output changes concordantly with right auricular pressure but this concept has recently been criticized (20, 21). In our experiments there was no relationship between mean right auricular pressure and stroke volume, pulmonary arterial pressure, blood pressure or work of the right heart in either the cooled or the control series. Changes in the mean right auricular and mean pulmonary arterial pressures usually occurred in the same direction but were not proportional and on occasion the direction of change was discordant.

Hemoconcentration

Hematocrits were taken periodically in 10 dogs. It should be noted that about 100 to 150 cc. of blood were withdrawn and replaced with isotonic saline solution during each experiment. There was an average increase in the hematocrit value of 10% at the lowest temperatures with a tendency to hemodilution during rewarming. Barbour (22) has demonstrated a reflex which originates in

chilled skin and is mediated via the hypothalamus, to produce a shift in the body fluids from the circulating blood to the interstitial spaces in hypothermic states.

Causes of death

Five animals died in the course of these experiments. Cardiac failure has been suggested as a cause of death in hypothermia in man (23), in dogs (5) and in rats (17). However, this view is not substantiated by our observations. One death was due to ventricular fibrillation which occurred early in the cooling period; ventricular premature beats were frequent from the onset of the experiment and in this case an irritating effect of the intracardiac catheter could not be excluded. In three dogs there was a sudden fall of blood pressure prior to the cessation of respiration. This occurred during rewarming at body temperatures of 35° C in one dog, at 34° C, in another, and in the third dog it occurred at 27.5° C. Marked bradypnea and respiratory irregularity developed soon after the blood pressure fell and respiration ceased shortly thereafter. In these dogs the pulse rates were 146, 120 and 90/min. respectively, and the cardiac outputs were at high levels during the period immediately preceding the fall in blood pressure. We must conclude that in such cases there was a sudden vasomotor paralysis. In the fifth dog there was a primary central respiratory arrest. A sudden anoxic rise in blood pressure occurred and this was followed by a progressive fall in pressure. In this case the vasomotor center was able to respond to anoxia in a normal manner. Artificial respiration was instituted and the heart continued to beat for about two hours after respiratory arrest. Therefore, in our cases death was due to failure in the central nervous system either of the respiratory or of the vasomotor centers, as stated in some other reports (5, 24). In more prolonged and more intense hypothermia employed by others, other causes may be involved.

GENERAL COMMENTS

The present studies, correlated with those of other investigators, make possible a more complete analysis of the hemodynamic changes occurring during hypothermic states. Figure 2 represents a composite graph in which the relationship between the hemodynamic factors which we have

died and changes in body temperature can easily be seen. The general effect of cold on all body tissues is to reduce progressively all cellular metabolic processes in accordance with van't Hoff's Law. Early in the cooling period of a warm blooded animal such as the dog, reflexes are stimulated which tend to decrease the loss of heat and to increase the rate of endogenous heat production, thus tending to maintain the body temperature at normal levels. Some of these reflexes result in a reduction in peripheral blood flow, shivering and redistribution of body fluids. The cardiovascular response during this early period is manifested by tachycardia, elevated blood pressure and increased cardiac output, as was observed early in the cooling of the lightly anesthetized animals. Anesthesia tends to inhibit these protective reflexes to some extent but shivering can be seen in most anesthetized animals during cooling.

As cooling becomes more intense and more prolonged there develops a progressive bradycardia, bradypnea, decreased oxygen consumption, decreased cardiac output and hypotension. The metabolic demands of the tissues for oxygen and substrate are so markedly decreased that true anoxia must be minimal despite a reduced availability of oxygen. This accounts for the failure of the administration of 100% oxygen to be of benefit or to prolong life during hypothermia. At very low body temperatures a progressive respiratory center depression occurs, due to the effect of cooling, and in our experiments to the effect of anesthesia. This depression may markedly reduce the oxygen supply and lead to the death of the animal in anoxia. During this phase of respiratory failure, oxygen and artificial respiration should be of value.

The depressant effect of cold on all body tissues holds true for the myocardium itself. This is reflected by the development of progressive sinus bradycardia, abnormalities in depolarization and later in repolarization, prolongation of electrical systole and the development of intraventricular block, as well as prolongation of auriculo-ventricular conduction time. The direct effect of cold on the heart is well shown by the development in the isolated heart preparation of changes similar to those described above. We observed no evidence of an inability of the heart to deal satisfac-

torily with the venous return of blood from the periphery.

The marked decrease of cardiac output which occurred during cooling is primarily the result of changes in the peripheral circulation. There is a progressive decrease in the circulating blood volume with the development of hemoconcentration, due to a shift of body fluids from the vascular bed into the interstitial spaces. These factors tend to reduce the venous return to the heart and to decrease the cardiac output. There are certain compensatory mechanisms, however, as is shown by the maintenance of the blood pressure at relatively high levels in the face of a markedly reduced cardiac output. These facts may thus be considered as evidence that marked peripheral vasoconstriction occurs, partially compensating for the decreased blood volume and cardiac output. When these compensatory mechanisms fail to meet the stress produced by hypothermia, vasomotor collapse occurs and leads to death.

All the changes which we observed were entirely reversible upon rewarming, and the recovery of function was in general related to the degree of rewarming accomplished. Thus the heart and respiratory rates, the blood pressure and the cardiac output tended to return to control values as the animal approached its normal body temperature. This would suggest that the induction of hypothermia in a warm blooded animal such as the dog may not be an altogether unphysiological procedure, in the sense that the compensating adjustment patterns, which appear during the cooling and the rewarming periods, are ordinarily capable of coping with the situation, within limits.

SUMMARY

1. Circulatory changes and cardiac output were studied in 12 dogs during cooling induced by exposure to chipped ice packs and during rewarming, and in three control dogs.
2. During the early cooling period, thermogenic reflexes which cause shivering are set off which act to produce an increase in oxygen consumption, respiratory and heart rates, blood pressure and cardiac output. These reflexes may be inhibited to some extent by deep anesthesia.
3. As cooling continues, and the combined pressing effects of hypothermia and anesthesia, hemoconcentration and a progressive fall in

gen consumption, in respiratory and heart rates, and in blood pressure occur. The cardiac output also falls. Marked prolongation of electrical systole, with the occurrence of intraventricular and A-V block, and changes in the S-T-T contour are seen. The changes in these values are related to the degree of hypothermia obtained.

4. During rewarming, these effects are reversed with a return of the blood pressure, respiratory rate, and pulse rate to normal, and with a tendency to a return to normal in the degree of hemocentration and cardiac output. Electrocardiographic changes were also reversed.

5. When it occurred, death in hypothermia was attributable to failure of the vasomotor or respiratory centers, rather than to failure of the heart.

6. No consistent correlated changes in right auricular pressure, on the one hand, and pulmonary arterial pressures, cardiac output, or the work of the right heart, on the other, were observed during either the cooling or rewarming periods.

THE CIRCULATORY RESPONSES TO HYPERTHERMIA INDUCED BY RADIANT HEAT¹

By O. PREC,² R. ROSENMAN, K. BRAUN,³ R. HARRIS, S. RODBARD,
AND L. N. KATZ

(From the Cardiovascular Department,⁴ Medical Research Institute, Michael Reese Hospital, Chicago)

(Received for publication July 19, 1948)

An elevation of the body temperature evokes many physiological changes, as a direct result of the increased rate of metabolism and the greater demand for oxygen and substrate, and indirectly in warm blooded animals because of the elicitation of thermolytic mechanisms. An understanding of the interrelationships between these factors is of obvious importance in an appreciation of the dynamics of hyperthermia and in the establishment of a rationale for its treatment. Despite many important contributions to this problem, there is a paucity of information concerning the effect of hyperthermia on the cardiac output and the right intracardiac pressures. We have therefore undertaken an analytical study of the circulation in hyperthermia in an effort to assay these adjustments more satisfactorily. Our present experiments have been limited to a study of the changes which occur following exposure to radiant heat since this method of producing hyperthermia seemed to be the simplest, being free from incidental effects produced by pyrogens and by other methods. A few experiments were done with short wave diathermy.

METHOD

Hyperthermia was induced in nine dogs. Six dogs, anesthetized with sodium pentobarbital, were exposed to radiant heat from several light bulbs until the body temperatures (about 38° C) gradually increased to 42° C during a two-hour interval. Body temperatures were reduced during the following one- to two-hour periods by using cold wet cloths applied to the body and by draft-producing electric fans. Temperatures were obtained from a thermometer placed deeply in the rectosigmoid area. A mercury manometer attached to a

femoral artery recorded mean arterial blood pressures on a kymograph. Mean pulmonary arterial and right auricular pressures were obtained with saline manometers attached to their respective radio-opaque cardiac catheters. Cardiac output was calculated according to the Fick formula, blood from the pulmonary artery being used as mixed venous blood, and oxygen consumption being recorded with a basal metabolism apparatus attached to the cannulated trachea. Hematocrits of the arterial blood were determined according to the method of Wintrobe. Blood O₂ and CO₂ analyses were performed by the Van Slyke-Neill technique. A detailed description of these methods is given elsewhere (1). Measurements similar to the above were also obtained in a series of three dogs heated by short wave diathermy,⁵ but unless specified, the results given below refer only to those experiments in which radiant heat was employed. Similar measurements were made on three control anesthetized dogs kept at room temperature.

DISCUSSION OF RESULTS

Oxygen consumption

Many studies have demonstrated a close parallel between the rise in body temperature and the increased oxygen consumption (2-4) which accompanies the acceleration of cellular metabolism during fever. In our experiments (Figure 1) an average increase of 57% was observed at a body temperature of 42° C, the greatest increase being 100% in one instance. During the cooling period oxygen consumption decreased simultaneously with the fall in body temperature and returned to control levels as the temperature of the animal again reached 38° C. In the control series only slight and insignificant changes in oxygen consumption took place.

Respiration and content of blood gases

The production of hyperthermia was accompanied by an increase in respiratory rate and

volume (Figure 1) similar to that which has been reported in all types of naturally occurring fever (2). During recooling the respiratory rate and volume decreased proportionately to the temperature fall. It is of interest to note, however, that greater than normal rates and volumes of respiration persisted even after the conclusion of the cooling period and the return of body temperature to control levels. This effect may have been due to the greater rate of destruction of the anesthetic agent during the febrile period and a consequent heightened activity of the respiratory center. In the control series no significant changes were noted.

Differences in the respiratory response were noted, depending on the type of heating used. With radiant heat the respirations were regular and only slightly decreased in depth. When the fever was produced with short wave diathermy, respirations became shallow and grossly irregular. The hyperpnea was probably due to the increased CO_2 production in the tissues, the increased activity of the respiratory center itself, and the initiation of thermolytic reflexes. It has been reported that extreme tachypnea and shallow respiration may seriously interfere with the exchange of alveolar air, and thus decrease the arterial oxygen content (3, 5). However, the slope of the oxygen consumption curve in our experiments indicated that the diffusion of oxygen in the lungs was not impaired when radiant heat was employed. With diathermy, the slope of the curve was highly irregular. It was because of this

irregularity that the results obtained with diathermy were not treated in the present study.

The arterial oxygen content varied only slightly during our experiments with an average decrease of 0.8 vol.%. The large difference in dog H5 (Table I) was associated with a simultaneous increase in hematocrit. No significant changes were noted in the control series. Others have reported decreases in arterial oxygen content during hyperpyrexia (3, 6) with a relatively greater decrease in venous blood oxygen content (3).

The effect of hyperpnea on the CO_2 content of the arterial and venous blood should be emphasized. Figure 2 shows that as the respiratory rate increased, the CO_2 content of the arterial blood decreased. The curve for venous blood is similar to that of arterial blood but shifted to the right. The primacy of the thermolytic mechanism which is effected chiefly by panting in the dog is seen by the marked reduction of blood CO_2 and the consequent alkalotic tendency. Despite this tendency to alkalosis, the respiratory rate continued at high levels.

Arteriovenous oxygen difference

The oxygen content of the arterial and venous bloods is given in Table I. It can be seen from

FIG. 2. A GRAPH SHOWING THE RELATIONSHIP BETWEEN THE BODY TEMPERATURE, RESPIRATORY RATE, AND THE CARBON DIOXIDE CONTENT (VOLS.%) OF ARTERIAL AND VENOUS BLOOD DURING THE WARMING PERIOD FROM 37° TO 42° C

T represents temperature.

it that the utilization of oxygen increased proportionately to the rise in body temperature despite the progressively reduced cardiac output (Figure 1). The average arteriovenous oxygen difference was 6.1 vol.% at 36° to 38° C and increased to 11.3 vol.% at 42° C, remaining high in some instances or even increasing during the re-cooling period. The increase in A-V oxygen difference was relatively greater than the increase in oxygen consumption. These findings are in general agreement with those of Uyeno (3).

Hematocrit

Approximately 100 cc. of blood were removed and replaced by isotonic saline solution during each experiment. Hematocrits of arterial blood samples showed no consistent trends. During fever it has been reported (7) that there is usually an initial hemodilution with increased blood volume.

Cardiac output

Two of the most important factors which must be assayed in order to understand the circulatory changes which occur during exposure to radiant heat include the simultaneous measurement of the cardiac output and the blood pressure. In our experiments the cardiac output decreased consistently with fever (Table II) in all but two animals in which a transient rise occurred at the beginning of the warming period. The output began to decrease early or immediately after the heat was applied. In the two dogs H2 and H4, the cardiac output decreased markedly while the temperature was rising from 36° to 38° C (from 1396 to 821 cc., and from 1300 to 712 cc./min., respectively). The relatively greater increase in the arteriovenous oxygen difference compared to

that of the oxygen consumption accounted for the decreased cardiac output which occurred in the face of increases in oxygen consumption and pulse rate.

Electrocardiographic studies (2, 8) and the transitory character of the changes during fever suggest that the conduction system of the heart is apparently not damaged in short-lasting fever. We may therefore assume that the changes in cardiac output during fever were determined primarily by a decreased venous return rather than by cardiogenic factors. The decreased venous return is probably an early result of redistribution of blood which may later be accentuated by the markedly reduced blood volume resulting from the fluid loss consequent to heating. Some decrease in cardiac output was noted in the controls due partly to the anesthetic and partly, perhaps, to the spontaneous fall in body temperature of one to two degrees (1).

During recooling the cardiac output continued to decrease significantly, even after body temperature had fallen to control levels (Table II). This would suggest that the febrile period sets up mechanisms which reduce the cardiac output, and that these mechanisms may persist for a time after the cessation of the heating period.

Blood pressure

Blood pressure changes seen during the induced fever were variable (Figure 1). In four dogs an initial and progressive fall occurred. In one, no change in pressure occurred and in one there was an initial rise followed by a fall. The greatest fall in pressure was 57% of the original level. In two of the three dogs heated with short wave diathermy the blood pressure tended to rise and then remained at the higher levels, findings similar to those reported by Wiggers and Orias (9).

Since the blood pressure is the resultant of a number of factors, the effect of heating on each of them must be considered in the interpretation of results. Among the more important are the decreased cardiac output, an increase in the vascular bed due to vasodilation in various portions of the body, and neurogenic factors which tend to increase the peripheral resistance and thus maintain the blood pressure. The apparent contradiction in the latter two factors may be resolved on the

basis of regional differences in vascular tone. This mechanism deserves further analysis. In the control series, a slight decrease in blood pressure occurred probably due to the anesthetic and to the spontaneous fall in body temperature (1).

Pulse rate

A close correlation between body temperature and pulse rate has been shown (2). Acceleration of the pulse rate is effected by the direct action of the increased temperature on the sinus node which remains the pacemaker even during very rapid rates (10). The rate increases as much as 92 beats per minute at 42° C, averaging 39 (Figure 1). No significant changes were noted in the control series. An acceleration of the pulse rate is obviously not necessarily associated with an increase in cardiac output since other factors play more dominant roles (11).

Intracardiac pressures

The pressure in the right auricle was measured in four dogs and showed steady and substantial decreases (Figure 1). The pressures continued to fall during the cooling period and at the end of the experiments were as low as 4 cm. saline below the control levels. Large variations in both directions were seen in the pulmonary arterial pressure in both the heated and control series. The changes in the right auricular pressures in the control group were inconstant, varying only slightly from control levels.

DISCUSSION

The data collected during our experiments represent an analysis of the circulatory responses to exposure to an intense radiant heat. The mechanism of the rise in body temperature induced by exposure to radiant heat is essentially that of a prevention of heat loss (12). There is no doubt that adaptation will be different following exposure to different types of heat.

The generalized application of intense radiant heat was followed shortly by a progressive fall in cardiac output, regardless of the elevated body temperature, oxygen consumption and the heart rate. It has too often been assumed that cardiac output invariably increases during fever (2, 10). While the output may increase in certain circumstances (3, 4, 6) recent ballistocardiographic stud-

ies have failed to demonstrate an increase during fever (13) and others have suggested that the output may be reduced in hyperthermic states (9, 14). Our results demonstrate that in induced fever due to radiant heat, the cardiac output is usually diminished and that this is a dominant factor in the ensuing circulatory changes.

In hyperthermia produced by high external temperature, marked vasodilatation occurs in the cutaneous and other vascular beds (2). Large amounts of blood may therefore be shifted to the periphery, resulting in a decreased volume of blood available for venous return to the heart. This is indicated by the falling venous pressure which we observed in our hyperthermic animals. The increased respiratory activity associated with an excessive internal temperature and the loss of body fluids both contribute to decrease further the effective blood volume. These changes also lead to a reduction in venous return and so to a further reduction in cardiac output, in proportion to the duration and intensity of exposure to radiant heat.

Many explanations have been advanced to explain the circulatory collapse in heat stroke and these have been reviewed recently by Daily and Harrison (4). These include hemoconcentration, reduction of blood volume, increased intracapillary pressure resulting in increased fluid transudation and cardiogenic vascular collapse. Wiggers and Oria (9) have demonstrated a reduction in systolic discharge and a decrease in the force of ventricular contraction when the body temperature rises above 41° C due to exposure to radiant heat. Our results suggest that the normal heart is not significantly injured by hyperpyrexia and appears to be able to cope adequately with the venous return from the periphery.

Previous experiments in this laboratory (1) have re-emphasized that both man and animals may undergo prolonged exposure to cold with reduction in body temperature as great as 12° C in the dog, with complete recovery in most instances following rewarming. Tolerance to elevated body temperature is therefore considerably less than tolerance to cooling. Thus, in the dog, survival after a rise in temperature of 5° C will be rare and even lesser elevations of body temperature may be sufficient to embarrass the cardiovascular system.

When the febrile animal was permitted to lose heat, the body temperature rapidly returned to normal but the cardiac output continued to decrease. Evidently mechanisms initiated during the hyperthermic phase which reduced the cardiac output persisted during the phase of return to normal body temperature. Rational therapy should therefore be directed to measures which would increase the cardiac output to normal values during the cooling phase. Simple reduction of the body temperature to normal obviously would be inadequate since the cardiac output remains markedly reduced and peripheral circulatory failure may result in death.

SUMMARY

The changes in the cardiovascular system were studied in anesthetized dogs during acute hyperthermia induced by intense radiant heat and during the return of body temperature from 42° C to normal.

During the warming period the oxygen consumption increased markedly, rising to about 150% of normal at 42° C. The cardiac output was progressively reduced. As a consequence the arteriovenous oxygen difference was increased. The blood pressure was maintained at relatively normal levels in the face of an apparent increase in the capacity of the vascular bed and a coincident decreased cardiac output, indicating an active vasoconstriction process. The heart rate increased progressively with hyperthermia and the right auricular pressure tended to fall.

During the recooling period the oxygen consumption, respiratory rate and heart rate returned toward normal levels. The cardiac output and right auricular pressure continued to decline significantly even after the body temperature had returned to control levels. The blood pressure was maintained in most of the animals. No significant changes were found in the pulmonary arterial pressure.

During hyperthermia the heart appears to be able to cope with the venous return. Our experiments therefore suggest that the circulatory changes occurring in acute hyperthermia depend upon (1) an increased demand for blood by the tissues which leads to (2) an increase in the volume of the vascular bed. Since (3) the circulating blood volume and venous return do not in-

crease proportionately and may even decrease, a marked reduction in cardiac output occurs. (4) If the blood pressure and the circulation are to be maintained vasoconstriction must occur. Failure of the vasomotor centers to compensate for the progressively reduced cardiac output prepares the ground for peripheral vascular collapse.

THE RELATION OF INFLUENZA VIRUS AND BACTERIA IN THE ETIOLOGY OF PNEUMONIA^{1, 2}

By ELIZABETH STARBUCK MAXWELL, THOMAS G. WARD, AND
THOMAS E. VAN METRE, JR.

(From the Department of Bacteriology, School of Hygiene and Public Health, and the
Department of Medicine, School of Medicine, The Johns Hopkins University)

(Received for publication August 9, 1948)

Evidence is accumulating that influenza virus plays a role in the etiology of certain pneumonias generally considered to be primarily bacterial in origin. The earliest recorded observations (1, 2) describe influenza as a mild self-limited disease of the upper respiratory tract which progressed occasionally in certain individuals to produce more serious symptoms involving the pulmonary tissue. Soon after the discovery of bacteria, clinicians (3) pointed out that pneumonia caused by streptococci, staphylococci and pneumococci often followed symptoms of influenza.

During the pandemic of 1918 influenza was frequently complicated by bacterial pneumonia. Certain investigators (4, 5) believed that the primary disease was of unknown virus etiology and that the pulmonary involvement was a manifestation of the secondary invasion of the respiratory tissues by pathogenic organisms.

Epidemiological data (6-10) show a significant increase in pneumonia deaths accompanying and following epidemics of clinical influenza. Other similar data (11, 12) indicate that localized epidemics of pneumococcus pneumonia have been associated with outbreaks of clinical influenza.

Laboratory evidence (13-22) on clinical cases of bacterial pneumonia in man and experiments on laboratory animals (23-28) during the past decade have further supported these observations.

The studies reported herein show that there was a simultaneous infection with pneumococci and influenza virus in about one-half of the human cases of lobar pneumonia studied during an influenza epidemic. Such mixed infections were also observed during interepidemic periods.

¹ This study was supported in part by a grant from the Division of Research Grants and Fellowships, National Institutes of Health, U. S. P. H. S., Bethesda, Md.

² Read in part at the annual meeting of the American Society for Clinical Investigation, May 3, 1948.

MATERIAL AND METHODS

Source and preservation of specimens

Sputum: Specimens of sputum were obtained from 69 cases of bacterial pneumonia admitted to hospitals in the Baltimore area between November 30, 1946 and August 5, 1947. The group included 61 cases of pneumococcal pneumonia, three cases of pneumonia due to Friedlander's bacillus, and five cases which were diagnosed clinically as bacterial pneumonia but in which the causative organism was not identified. Sixty-four were clinically lobar pneumonia and five were broncho-pneumonia. Sixty-two of the specimens were from the Osler Medical Clinic of The Johns Hopkins Hospital. These cases are believed to represent an unselected sample of the 75 cases of bacterial pneumonia which hospital records show were admitted to the Osler Clinic during this period. The other seven specimens were obtained from either Sinai Hospital or from the Veteran's Hospital, Fort Howard, Maryland.

Thirty-six of the 69 cases (52 per cent) occurred during March and April 1947, when influenza "A" was known to be prevalent in the community as indicated by an increase in upper respiratory disease and by the frequent isolation of influenza virus. The occurrence of this outbreak afforded the opportunity to classify the cases into two groups (1) interepidemic, those occurring before and after March and April 1947, and (2) epidemic, those occurring during March and April. This classification with respect to the influenza epidemic is used throughout this report.

The sputa were mixed with beef heart infusion broth, pH 7.4, and were either inoculated immediately into embryonated hen's eggs or were frozen in sealed glass ampoules and stored at -20°C until they could be examined for the presence of influenza virus. The maximum period of storage was approximately four months.

Acute and convalescent sera: Acute and convalescent blood specimens were obtained from 53 of the 69 patients. The acute specimens were collected soon after admission to the hospital, and the convalescent specimens were secured just prior to discharge, approximately six to ten days later. A third specimen was collected about five months later from 25 of the cases. Serum from these specimens was inactivated by heating for 30 minutes at 56°C , frozen in rubber stoppered glass ampoules and stored at -20°C until it could be examined by the red cell agglutination-inhibition technique for antibody activity against various known strains of influenza virus.

Autopsy material: Specimens of lung and bronchus were obtained at autopsy³ from 86 persons dying in Baltimore³ between December 1946 and October 1947. In addition one specimen was obtained from a person dying of pneumonia in May 1946. Of the 87 specimens, nine were from persons in whom death was believed to be due directly and primarily to pneumonia, 28 were from persons with pneumonia which was believed to be secondary to some other condition, and 50 were from persons who had no evidence of pneumonia. Classification was made on the basis of clinical and pathological data in the hospital and autopsy records. The group whose death was believed to be due primarily to pneumonia includes six cases of pneumococcal pneumonia and three cases which may not have been bacterial in origin since the causative organism was not identified. The group of secondary pneumonia consists of terminal or aspiration pneumonias and pneumonias first detected at autopsy. The third group includes only cases in which there was neither clinical nor pathological evidence of pulmonary pneumonia.

A 25 per cent suspension of the lung and bronchial tissue was made by emulsification with beef heart infusion broth in a Waring blender. The suspension was centrifuged to remove large particles of tissue and the supernatant was stored at -20°C in sealed glass ampoules until it could be examined for the presence of influenza virus. The maximum period of storage was approximately six months.

Virus isolation

Both sputum and lung specimens were examined for influenza virus by the same technique. Five hundred units of penicillin and 5000 μg . of streptomycin were added to each milligram of the specimen and about 0.4 ml. of this mixture was inoculated into the amniotic sac (29) of 12 or 13 day old chick embryos. Ten embryos per specimen were used for the first egg passage and six for each additional passage.

The embryos were incubated at 35°C for four days. On the fourth day amniotic fluid and embryos were harvested. The amniotic fluid was tested for the presence of influenza virus by the pattern agglutination technique (30) using chick and guinea pig red blood cells. If the fluid was negative by this test the lungs and tracheas of the embryos were removed and ground in a mortar with the homologous amniotic fluid. Penicillin and streptomycin were added to the mixture and this material was passed amniotically to 12 or 13 day old embryos. Three egg passages were carried out before a specimen was considered negative.

In an attempt to detect possible laboratory cross infection six embryos were inoculated with sterile broth at the same time each group of specimens was examined. The broth control was carried along with the specimens through three egg passages of six embryos each.

³ All autopsy specimens were obtained through the Department of Pathology of The Johns Hopkins Hospital and Medical School.

Identification of viruses

Amniotic fluids which gave positive tests by the pattern technique referred to above were inoculated into the allantoic sac of 10 or 11 day old chick embryos. Inoculated embryos were incubated for two days at 35°C , chilled overnight at 4°C , and the allantoic fluid harvested. Serial passage by the allantoic route was continued until allantoic fluid with a sufficient concentration of virus could be obtained for identification by the hemagglutination-inhibition test (31). A suitable antigen was usually obtained by the fourth egg passage.

Known influenza immune sera used in identification of viruses were prepared by subcutaneous inoculation of chickens with the following strains of influenza virus: the PR8 strain of influenza A, the Lee strain of influenza B, a strain of influenza A (F47A7)⁴ isolated from an uncomplicated case of influenza during the 1947 epidemic in Baltimore, a strain of influenza A (P47A7) isolated from the lungs of a case of pneumonia in January 1947, and a strain of swine influenza virus.

Some of the strains, particularly those isolated during March and April 1947, proved difficult to identify as either A or B using this technique. Three of these strains (P47A2, P47A7, P47A8) were selected for further study employing acute and convalescent sera from cases of influenza occurring during three different epidemics: the 1943 influenza A epidemic,⁵ the 1945 influenza B epidemic, and the 1947 influenza epidemic during which two of the three strains were isolated.

Serological tests

Serum was tested by the hemagglutination-inhibition technique (31) using known strains of influenza virus as antigen. The strains of influenza virus routinely used as antigen in these tests were the PR8 strain of influenza A, the Lee strain of influenza B, two recently isolated strains of influenza A (one [P47A2] from a fatal case of pneumonia occurring in January 1947 and one [F47A7] from an uncomplicated case of influenza in March 1947), a strain of influenza B (P47B2) from a case of pneumonia in January 1947, and a strain of swine influenza.⁶ In order to rule out the effects of variations in antigen concentration and variation in red cells used from time to time, all sera whose titers were to be compared were tested simultaneously.

⁴ The method of strain designation for influenza virus isolated in this laboratory is as follows: The first letter stands for the disease from which the virus was isolated (F = uncomplicated influenza; P = pneumonia). The first two numbers represent the year of isolation. The second letter refers to the type of influenza virus (A = influenza A; B = influenza B). The last number is the order of isolation in the laboratory. Thus F47A7 is the seventh strain of influenza isolated in this laboratory in 1947 from uncomplicated influenza.

⁵ These sera were obtained through the courtesy of Dr. Thomas Francis, Jr., Ann Arbor, Michigan.

⁶ Dr. Richard Shope, Princeton, New Jersey, kindly furnished his Strain 15.

TABLE I

Influenza virus isolation and serological data on specimens collected from clinical cases of bacterial pneumonia

Time of occurrence with respect to influenza	Virus isolation			Serological studies			Total		
	No.	No. pos.	% pos.	No.	No. pos.	% pos.	No.	No. pos.	% pos.
Interepidemic	33	1	3	22	0	0	33	1	3
Epidemic	36	13	36	33	12	37	36	17	47

On the basis of serological results using the six antigens above, the cases of pneumonia were divided into four categories:

(1) Those in which the convalescent specimen when compared with the acute specimen showed a three-fold or more increase in titer to at least one of the strains of influenza A, but not to either strain of influenza B used as antigen.

(2) Those in which the convalescent specimen showed less than a three-fold increase in titer but in which the third specimen when compared with the convalescent specimen showed a four-fold or greater decrease in titer to at least one of the strains of influenza A, but not to either strain of influenza B.

(3) Those in which the third specimen when compared with the convalescent specimen showed at least a four-fold decrease in titer to both influenza A and influenza B antigens.

(4) Those in which there was neither a three-fold increase nor a four-fold decrease in titer to any of the antigens used in the test.

Since no specific increases or decreases in titer were obtained with the influenza B antigens it is not necessary to include these categories.

The cases in Group 2 were classified as pneumonia with positive serological evidence of recent or concomitant infection with influenza A. Specific decrease in titer over a period of months has previously been used (15) as the basis for serodiagnosis of infection with influenza virus, but the procedure is not so well established as that of diagnosis on the basis of specific increases in titer over a short period of time from the acute stage of the disease to early convalescence. In this laboratory it was observed that in a number of instances the convalescent specimen when compared with the acute specimen showed a non-specific decrease in titer to all the antigens employed in the test. Sometimes as much as a three- or four-fold decrease was noted. The cause of this non-specific decrease is entirely unknown. Since such a decrease would tend to mask specific increases in titer it would not give false positive results in category number 1. It would, however, tend to magnify specific decreases in titer if the third specimen were compared with the acute specimen. For this reason in making positive diagnoses on the basis of decreases in titer, the third specimen was always compared with the second, or with the convalescent specimen rather than with the acute specimen. Because of the uncertainties involved in diagnosis on the basis of specific decreases in titer over

a period of several months it was felt that only four-fold or greater decreases should be considered as serological evidence of infection with influenza virus.

The cases in Group 3 were classified as pneumonia with doubtful serological evidence of infection with influenza virus. Only two cases fell in this group. The significance of these doubtful results is difficult to determine. They may represent inherent inaccuracies in the test or they may be the result of anamnestic reactions. On the other hand, they may be indicative of actual infection with influenza virus. In the latter case their nonspecific nature might be explained either on the basis of infection with a strain of influenza virus with broad antigenic characteristics or on the basis of infection with more than one strain of influenza virus during the interval of several months.

The cases in Group 4 were classified as pneumonia with no serological evidence of infection with influenza virus.

RESULTS

Clinical cases of bacterial pneumonia

Isolation of virus

The results of both virus isolation and serological studies in the 69 cases of bacterial pneumonia investigated are shown in Table I.

Of the 33 specimens collected during the interepidemic period only one was positive by virus isolation. This was a specimen of sputum obtained on the fifth day of disease from a case of Type I pneumococcal lobar pneumonia occurring in January 1947. A strain of influenza B (P47B2) was isolated from this sputum on the first egg passage. Influenza virus was not isolated from a second sputum obtained on the seventh day of disease. On retesting the original sputum which had been stored at -20°C for two weeks influenza B was again isolated on the first egg passage. The other strain of influenza B (P47B1) was isolated from the lungs of a fatal case of pneumonia which also occurred in January of 1947. This case will be discussed later. During the interval between December 1945, at which time there was an epidemic of influenza B in Baltimore, and the time of isola-

tion of these two strains of influenza B, approximately 100 specimens of nasal washings from persons with upper respiratory infections had been inoculated into chick embryos. In no instance was influenza virus detected.

Influenza virus was isolated from 13 of the 36 cases of bacterial pneumonia which occurred during the influenza epidemic in March and April, 1947. The cases from which these strains of virus were isolated were all classified as pneumococcal pneumonia. Two were bronchopneumonia and the others were lobar pneumonia. Six were shown to be due to Type I, two to Type XXV, one to Type II, one to Type IV, and two to untyped pneumococci. Both Type IV and Type XXII were present in the sputum in one case. In these 13 positive cases sputum specimens were obtained from the first to the 20th day after the onset of clinical symptoms of pneumonia (see Table II).

In this small series of cases there is no correlation between day of disease and ability to isolate virus from sputum. The fact that virus was isolated from six specimens on or after the fifth day of pneumonia is somewhat surprising because it is generally believed that the virus is demonstrable in nasal or throat washings from uncomplicated influenza only early in the disease.

The isolation of influenza virus beyond the expected time in these complicated cases of mixed virus and bacterial infection may be explained on the basis that the virus in conjunction with the pathogenic bacterium descends to the lower respiratory tract, persists and probably multiplies in the respiratory epithelium of the bronchial tree longer than it ordinarily persists in the epithelial cells of the upper respiratory tract.

Appropriate precautions were taken to prevent laboratory cross infections leading to false posi-

tive results. These are believed to have been adequate for the following reasons:

(1) All of the 13 strains isolated during the influenza epidemic were found to be similar to strains of influenza A isolated from uncomplicated cases of influenza occurring in Baltimore during the same period.

(2) In each case the influenza virus was isolated on the first egg passage.

(3) All of the strains upon original isolation showed certain characteristics of the "O" type virus (32) in that they had a much higher agglutinating titer for guinea pig red blood cells than for chicken red blood cells.

(4) Twelve of the positive sputa were retested after they had been stored at -20°C for approximately eight months. Virus was again isolated on the first egg passage from 11 of these. The 12th sputum was negative after two egg passages. It is believed that the long period of storage, during which time the specimens were allowed to thaw and refreeze at least once, might well account for the failure to reisolate influenza virus from this one case. The possibility that the first isolation of influenza virus from this sputum might have resulted from a laboratory cross infection must be considered. However, on original isolation this strain showed "O" characteristics, which usually do not persist beyond the first passage. Unfortunately, no second serum was obtained from this individual so that a confirmatory serological diagnosis could not be made.

(5) None of the 18 broth controls which were inoculated and passed in a manner similar to the sputum specimens was ever shown to be contaminated with virus.

(6) All strains gave low hemagglutination titers in the early egg passages which increased for five to six passages.

Serological studies

Acute and convalescent serum specimens were obtained from 22 of the 33 cases which occurred in the interepidemic periods. A third specimen was obtained from 10 of these. There were no positive serological results in this group. The three specimens of serum obtained from the one case which was positive by virus isolation gave negative results by all serological tests including the

test in which the homologous virus was used as antigen. This may be an indication that the influenza virus played no part in this particular patient's illness. However, it has been noted that a certain proportion of persons who have clinical influenza during proved influenza epidemics fail to show an antibody response (33-38). In this connection it is interesting to note that of 45 cases of uncomplicated influenza occurring during the 1947 epidemic from which virus was actually isolated, only 21 (39) showed a significant increase in titer when tested by the agglutination-inhibition technique. Therefore, it seems reasonable to believe that the influenza B virus might have played a part in the disease process even though it caused no increase in serum antibody content as measured by the hemagglutination-inhibition test.

There were two doubtful results obtained on the specimens in the interepidemic group. A case of clinical lobar pneumonia of undetermined cause, which occurred in February 1947, was tested serologically five months later and showed a four-fold decrease in titer to a current strain of influenza A as well as a six-fold decrease in titer to the Lee strain of influenza B. Another case of lobar pneumonia believed to be due to Type VIII pneumococcus, which occurred in July 1947, showed a decrease in titer to both influenza A and influenza B antigens after a period of three months.

Acute and convalescent serum specimens were obtained from 33 of the 36 cases which occurred during the 1947 epidemic of influenza A. A third specimen was obtained from 15 of these. Twelve positive serological results were obtained in these cases, 10 falling into Group 1 as described above, and two into Group 2. Of the 10 cases in which the convalescent specimen showed at least a three-fold increase to influenza A antigens seven were also positive by virus isolation. As previously stated these seven cases were pneumococcal pneumonia due to various types of pneumococci. The other three were also due to pneumococci. All three were classified clinically as lobar pneumonia. One was due to Type I and one to Type II. Both Type III and Type XI were present in the sputum of the third case. Of the two cases diagnosed serologically on the basis of a specific four-fold decrease, one was also positive by virus isolation. Both these cases were pneumococcal lobar pneumonia, Type I.

No doubtful results were obtained in the epidemic group. Twenty-three specimens, including three which were positive by virus isolation, were negative serologically.

Of the four strains of influenza A routinely used as antigen in the agglutination-inhibition test by far the greatest number of positive results were obtained with P47A2, a strain of influenza A isolated from the lungs of a fatal case of pneumonia which occurred in February 1947. Nine of the ten cases which fell into the first group of serological positives showed a three-fold or more increase in titer with this antigen. Seven of the ten were positive with F47A7, a strain of influenza A isolated from a clinical case of influenza in March 1947 and chosen in this laboratory as the reference 1947 influenza A strain. Only two of the ten showed a three-fold or more increase to PR8, and one showed a significant increase with a strain of swine influenza virus. Table III shows the results of ten serologically positive cases with the four influenza A antigens.

In summary, of the 33 cases in the interepidemic periods one was positive by virus isolation and none was positive by serological methods. Of the 36 cases in the epidemic period 13, or 36 per cent, were positive by virus isolation. Eight of these 13 were also positive by serological tests. In addition to these eight, four cases were positive by serological results but negative by virus isolation. Thus, a total of 17 cases, or 47 per cent of those occurring during the influenza epidemic, gave posi-

TABLE III

tive evidence of the presence of influenza virus associated with lobar pneumonia. All of these 17 cases were pneumococcal pneumonia. Eight were classified as Type I, two as Type XXV and one each as Types II, IV and XXII. Both Types III and XI were present in the sputum of one and Types IV and XXII in the sputum of another. Two cases were due to pneumococci whose type was not determined.

Virus isolation from autopsy material

The results of virus isolation from autopsy material are shown in Table IV.

TABLE IV

Influenza virus isolations from specimens of lung and bronchus obtained at autopsy from patients with pneumonia and with no pneumonia

Classification	Epidemic period		Inter-epidemic period		Total	
	No. cases	No. pos.	No. cases	No. pos.	No. cases	No. pos.
Primary pneumonia	2	0	7	2	9	2
Secondary pneumonia	7	0	21	2	28	2
No pneumonia	26	0	24	0	50	0

Influenza virus was isolated from two of the nine fatal cases classified as primary pneumonia. Both pneumococcus Type II and a strain of influenza A were isolated from the lungs of one of these cases (P46A1) which occurred in May 1946. In order to determine the quantity of virus present in the lungs of this case, titrations were made by inoculating chick embryos both by the allantoic route and by the amniotic route. The dose which would infect 50 per cent of the embryos inoculated was calculated using the method proposed by Reed and Muench (40). The EID_{50} for 11 day chick embryos inoculated via the allantoic route was $10^{-7.8}$. For 13 day embryos inoculated by the amniotic method an EID_{50} of $10^{-8.3}$ was obtained. These data indicate that virus was present in large quantities.

At the time of occurrence of this case, clinical and epidemiological evidence indicated that influenza A had not been prevalent in Baltimore for 2½ years and laboratory studies on upper respiratory disease for at least six months prior to the case had not disclosed influenza A in the population.

In January, 1947, in Baltimore, one year after the last known clinical case of influenza B, a strain of influenza B was isolated from the lungs of another fatal case of pneumonia (P47B1) and pneumococcus Type XI was isolated from the tracheal exudate three days before death.

The clinical and pathological aspects of these two cases will be discussed in another paper (41).

Influenza virus was isolated from the lungs of two of the 28 cases classified as secondary pneumonia. Both of the cases occurred early in February, just one month prior to the influenza A epidemic in Baltimore. One of the two strains (P47A1) of virus isolated was similar to strains isolated from clinical cases of influenza A during the epidemic. The other strain (P47A2) was also influenza A but it differed antigenically from the epidemic strain.

Lack of data makes it impossible to determine the exact nature of the pulmonary involvement of these two cases. There is, however, evidence in both cases which indicates that there was some pulmonary involvement. Since these cases will not be included in the subsequent paper a brief resume of the clinical and pathological data is given here.

One of the patients (P47A1), a colored male 14 months old, entered Sydenham Hospital with a diagnosis of chicken pox from the Harriet Lane Home of The Johns Hopkins Hospital. On admission his temperature was 103, pulse 176 and respirations 44. The uvula, the tonsils and the posterior pharynx were injected. The lungs were clear. The patient was given penicillin. After four days the temperature was normal and the throat injection had subsided. A systolic murmur was present over the base of the heart. Subsequently, this became more pronounced, spreading to the apex. On the ninth hospital day the patient died. The final clinical diagnosis was heart failure of unknown etiology, healed varicella, otitis media, and acute pharyngitis.

At autopsy wide-spread collapse in the posterior parts of both lungs was noted. There were small scattered areas of what appeared to be consolidation. The right auricle and ventricle were much enlarged.

Sections of the lung showed a condition compatible with chronic passive congestion. There were also small scattered foci of coagulative necrosis. The fresher ones seemed to be composed of

fibrin, a few mononuclear cells and some hemorrhage. The walls of the alveoli in these areas were necrotic. These lesions were said to be not unlike those previously observed (42) in a case of congenital varicella.

Unfortunately, no cultures were made from this lung and it is impossible to determine what part, if any, pathogenic organisms might have played in the disease process. It is also impossible to determine whether or not influenza virus itself played any part in the formation of the lung lesions found at autopsy.

The other fatal case (P47A2) classified as secondary pneumonia from which a strain of influenza A was isolated was a white male seven months old. This patient was referred to Sydenham Hospital with a diagnosis of bronchopneumonia of one day's duration. He was dead on arrival at the hospital. A cisternal tap showed cloudy fluid containing *H. influenzae*. The patient's older brother who was brought to the hospital at the same time was subsequently shown to have had meningitis due to *H. influenzae*.

At autopsy the lungs were found to be mostly air-containing. The pleural surfaces were smooth. The bronchial mucosa was covered by thin mucoid

material. On section the cut surfaces of the lungs showed numerous grayish areas separated by areas of red. In some areas the foci of consolidation appeared to be around the walls of the small bronchi.

Histological examination of these lungs failed to show any evidence of consolidation, bronchitis, or interstitial pneumonia.

As in the previous case no cultures from the lungs were reported. A culture made in this laboratory revealed no significant pathogen but the plates were contaminated with a gram negative rod believed to be *Aerobacter aerogenes*.

Titration in chick embryos were made to determine the quantity of virus in this lung. The EID_{50} was $10^{-2.8}$ with 11 day embryos inoculated allantoically. This is a minimum figure since the titration was made after the specimen of lung had been stored for six months at -20° C. During the storage period the specimen was known to have been thawed and refrozen at least once. The quantity of virus in the lung was therefore sufficient to suggest that the virus might have become established in the lung tissue. The role it played, either alone or with some undetermined bacterial agent,

in the production of the clinical symptoms cannot be determined on the basis of available data.

Strain identification

The results of hemagglutination-inhibition tests using known immune chicken sera with the various strains of virus isolated from sputum or lung specimens are shown in Table V.

Interpretation of these data is very difficult since the homologous titers of the various immune sera were different and since there was some unavoidable variation in the quantities of the different antigens used in the test.

It seems clear, however, that of the four strains isolated from the lungs of fatal cases of pneumonia one (P47B1) was a typical strain of influenza B and two (P46A1 and P47A2) were strains of influenza A which immunologically were very similar to each other, and somewhat similar to the PR8 strain of influenza A. Neither of these strains showed cross reactions with the Lee strain of influenza B. The fourth strain (P47A1) was inhibited to almost the same extent by both PR8 chicken antiserum and Lee chicken antiserum. It was inhibited by much higher dilutions of chicken antiserum to the strain chosen in this laboratory because of its early isolation and its antigenic similarity to subsequently isolated strains as the reference 1947 strain of influenza A (F47A7).

Of the 14 strains isolated from the sputum of nonfatal cases of pneumonia, one (P47B2) was a typical strain of influenza B. The other 13 strains, all isolated in March and April, 1947, were similar to each other and to the reference 1947 strain of in-

fluenza A (F47A7). They were inhibited to almost the same extent both by PR8 chicken antiserum and by Lee chicken antiserum.

The tests described above were carried out after the various strains had been passed only three or four times in chick embryos. Since it is known that antigen prepared from recently isolated strains may contain a substance which inhibits the agglutination of red blood cells in the presence of normal as well as immune sera (57) three strains (P47A2, P47A8 and P47A7) were selected for further study after repeated passages in chick embryos. After 12 embryo passages, the results were essentially the same as those obtained using antigens prepared from earlier egg passage material. Strain P47A2 was again inhibited, although to a small extent, by PR8 antiserum but not by Lee antiserum. Strains P47A7 and P47A8 were inhibited to almost the same extent by both PR8 antiserum and by Lee antiserum. They were inhibited to a greater extent by F47A7 antiserum.

By using the unidentified strains of virus as antigens in hemagglutination-inhibition tests with human acute and convalescent sera obtained from persons who had clinical influenza during three different proved influenza epidemics, somewhat more clear-cut results were obtained. The results of these tests are shown in Table VI.

On the basis of the results obtained with human acute and convalescent sera, the strains of influenza virus isolated from patients with pneumonia during the 1947 epidemic of influenza in Baltimore are believed to be more closely related to influenza A than to influenza B and to be very closely related to strains of influenza virus isolated

TABLE VI
Identification of selected strains of influenza virus using human acute and convalescent sera from three influenza epidemics

from uncomplicated cases of influenza occurring during the same period.

DISCUSSION

It seems evident on the basis of results obtained in these and other similar studies that often during influenza epidemics and occasionally during non-epidemic periods, bacterial pneumonia is in some way related to recent or concurrent infection with influenza virus. The pathogenesis of these multiple infections is not yet understood.

It seems unlikely that influenza virus alone is often responsible for severe pneumonia. During the 1918 pandemic a vast number of fatal cases of pneumonia were examined (4, 43-47) and in only two reported instances (47) was it impossible to isolate a pathogenic organism from the lungs. Since the discovery of the virus etiology of influenza a number of successful attempts have been made to isolate the virus from the lungs of fatal cases of pneumonia. In all but one of these (18) a pathogenic organism was also present in the lungs.

No pathogenic organism was isolated from the lungs of one of the fatal cases reported in detail in another paper (41) and the pathology in this case is that of pure virus pneumonia. A pneumococcus Type XI was isolated, however, from the tracheal exudate three days before the patient died of bronchopneumonia.

Influenza virus has been isolated from the sputum of non-fatal cases of pneumonia. In most instances the predominating organisms in the sputum from these patients were pneumococci or hemolytic staphylococci. However, there is clinical evidence that infections with influenza virus alone can cause slight abnormal pulmonary signs and might actually cause some patchy consolidation (22, 48). Reimann (49) in a review of pneumonias of viral origin states that pneumonia is an integral part of influenza but for unknown reasons influenzal lesions of the lung are more often invaded by pathogenic organisms than are the lesions of other viral pneumonias.

Probably the most generally accepted explanation concerning the relationship of influenza virus and bacteria in the pneumonias accompanying influenza is that the viral agent plays only a preparatory role. It is commonly believed that debilitating infections such as influenza decrease the general resistance of the host and predispose to bacterial

invasion. The mechanism by which general host resistance is lowered is not understood. A more clear-cut explanation for the lowering of local resistance in the respiratory tract can be given. It is known that influenzal infections in the ferret (50) and probably in the human (51) cause destruction of the ciliated epithelium of the respiratory tract. The destruction of this important local defense mechanism would be expected to facilitate invasion of the lungs by pathogenic organisms. Symptoms of pneumonia often have their onset a week or more after the first symptoms of influenza.

Although there is only slight evidence (26) to support such a concept, there is a possibility that the virus might act on certain potentially pathogenic organisms composing the normal flora of the nasopharynx in such a way as to increase their virulence and invasive ability. The invasive ability might be enhanced simply by the protective action against phagocytosis offered by mucus present as a result of influenzal infection. As reported herein, the isolation of influenza virus from 36 per cent of bacterial pneumonias occurring during an influenza epidemic indicates that the virus could have been playing an active part in the disease despite the onset of the pneumonia several days after the onset of clinical influenza. Both agents may be actively engaged in some as yet unknown relationship. Pathological manifestations of virus and bacterial complex infections are often similar regardless of the type of bacterium. The virus is thought to play a part in producing the pathological lesions and superimposed on such lesions are changes brought about by the bacterium.

Taylor (52) observed that a sublethal dose of influenza virus kills mice if followed in a day or two by intranasal instillation of sterile fluid. He proposed that the sterile fluid upset a delicate host-parasite relationship between spread of the virus and antibody production. By analogy such a mechanism might explain the simultaneous bacterial and influenza infections in man.

The inflammation produced by the bacterium may enhance release of the influenza virus from infected cells and aid in the spread of the virus to uninfected cells before the production of sufficient antibodies could prevent such a spread.

It is interesting to note that in five instances in the present study influenza virus was isolated from cases of pneumonia during interepidemic pe-

riods with respect to influenza. Sporadic cases of influenza have been reported by several investigators (20, 53-56) but there is not yet general agreement concerning the whereabouts of influenza virus between epidemic periods. Further investigation of bacterial pneumonias during periods when uncomplicated cases of influenza are not occurring to any great extent might indicate that influenza is indeed an endemic disease reaching epidemic proportions at more or less regular intervals. Why it was possible to isolate influenza virus from the sputum or lung of five cases of pneumonia and not possible to demonstrate the virus in nasal washings in any of about 100 cases of uncomplicated upper respiratory infections during the same interepidemic periods is not known. It may be that in cases of complex infection the virus descends to the lower respiratory tract and proliferates longer than it would in the upper respiratory epithelium. The number of uncomplicated cases from which nasal washings were examined represents only a small fraction of all the upper respiratory infections which occurred during the interepidemic periods and it is possible that more extensive studies would reveal sporadic cases of uncomplicated influenza as well as influenza complicated by pneumonia.

While these studies have been concerned with the simultaneous occurrence of influenza virus and bacteria in pneumonia, it is difficult to resist the speculation that other respiratory viruses, if and when techniques are available for their ready isolation and identification, will also be found in association with bacteria in other cases of pneumonia in man.

SUMMARY

1. Seventeen of 36 cases of pneumococcal pneumonia occurring during an epidemic of influenza A in Baltimore in March and April, 1947, yielded positive evidence, either by virus isolation or by serological studies of recent or concurrent infection with influenza virus.

2. All of the 13 strains of influenza virus isolated from these 36 cases were found to be similar to strains of virus isolated from uncomplicated cases of influenza occurring during the same period.

3. Influenza virus was isolated from the sputum of one of 33 cases of bacterial pneumonia oc-

curing during interepidemic periods. The one positive specimen was from a case of pneumococcal lobar pneumonia and the virus isolated was a typical strain of influenza B.

4. The lungs of two fatal cases of primary pneumonia and two cases of secondary pneumonia, in which no pathogenic organism was identified, yielded influenza virus. Three of the strains of virus were influenza A and one was influenza B. All four of these cases occurred during interepidemic periods with respect to influenza.

5. These studies indicate that influenza virus plays a role in the etiology of certain pneumonias which have hitherto been considered primarily bacterial in origin.

DETERMINATION OF THE PLASMA GLYCINE AFTER GELATIN FEEDING AS A DIAGNOSTIC PROCEDURE FOR PANCREATIC FIBROSIS

By HALVOR N. CHRISTENSEN AND HARRY SHWACHMAN

(From the Division of Laboratories, The Children's Medical Center, Boston, and Departments of Biological Chemistry, and Pediatrics, Harvard Medical School, Boston)

(Received for publication November 1, 1948)

A retardation of the absorption of amino acids derived from ingested protein into the bloodstream is known to result from a failure of the secretion of the pancreatic proteinases. West, Wilson and Eyles (1) have shown that a much smaller rise in blood amino nitrogen occurs in children with pancreatic fibrosis than in normal children after a test meal of casein. Preliminary results obtained by these authors indicated that gelatin might be a better test protein. To avoid a choice between the technically somewhat complex manometric ninhydrin procedure (Hamilton and Van Slyke [2]) and the analytically unsatisfactory colorimetric amino nitrogen methods (cf. Chinard and Van Slyke [3]) we have determined the plasma concentration of the single amino acid, glycine. Advantage is taken of the convenient method available for glycine (Alexander, Landwehr and Seligman [4]), the high glycine content of gelatin (25.5%), and the relatively slow disposition of this amino acid. Comparison of the fasting plasma glycine with the level 150 minutes after gelatin feeding provides a simple diagnostic procedure, although some qualifications will be noted below.

Although duodenal intubation in most cases is not a difficult procedure, upon occasion it may be troublesome. Mention might be made of a) several instances where four or five separate unsuccessful attempts were made to obtain a satisfactory specimen from a patient, b) the undesirability of the procedure in the severely ill infant, and c) the occasional febrile reaction following intubation. The present procedure offers an alternative diagnostic test.

EXPERIMENTAL

The test procedure is as follows: the patient is given, six to 12 hours after the last meal, 1.5 grams of protein per kilogram of body weight in the form of Knox gelatin, in 30 ml. of warm water per kilograms, either by mouth or by gavage. Venous blood is collected just

before the feeding and 2½ hours after. The plasma is separated *at once*, deproteinized with picric acid, and the glycine determined according to Alexander *et al.* (4). The analysis depends upon a colorimetric measure of the formaldehyde released from glycine by ninhydrin. A comparison of the optical densities of the two samples without translating them into glycine concentrations is sufficient.

For the deproteinization, 5 volumes of picric acid are added to the plasma, and the mixture centrifuged (Hamilton and Van Slyke [2]). When analyzing fasting blood, a 4 ml. aliquot of plasma filtrate is used; for the samples taken later, 2 ml. usually give a suitable depth of color. This means that 3 or 4 ml. of fasting blood and 1.5 ml. of the postprandial blood samples permit duplicate analyses. The requirements can be decreased if necessary to about 0.5 ml. of blood by cutting quantities used in half throughout the procedure, and distilling over to a volume of 5 ml. rather than 10 ml. A drop of normal sodium hydroxide is added for each 2 ml. of picric acid filtrate used in the determination, to neutralize the picric acid.

The patients studied ranged from one month to 12 years in age. In most cases the plasma glycine was determined before the test, and one and 2½ hours after the test meal. The total α -amino nitrogen in many cases was also determined for comparison.

RESULTS AND DISCUSSION

Three groups of patients were studied:

1. Twenty-four patients for whom the diagnosis of pancreatic fibrosis had been established, in 22 of them by the absence of tryptic activity in the duodenal contents.

2. Nineteen patients for whom the diagnosis of pancreatic fibrosis had been excluded. These were malnourished children, several of whom suggested the diagnosis of pancreatic fibrosis on clinical grounds.

3. Six patients whose clinical course was consistent with the diagnosis of pancreatic fibrosis, who had, however, definite although diminished tryptic activity.

TABLE I

The plasma glycine nitrogen following gelatin feeding
The values are averages for the group of patients indicated, and are in mg. N per 100 ml.

	Fast-ing	In-crease after 60 min.	In-crease after 150 min.	Ratio, 150 min. to fasting	
				Mean	Range
Controls (19)	0.26	0.90*	1.28	5.0	2.6 to 7.6
Pancreatics (24)	0.32	0.44†	0.59	1.9	1.2 to 3.2
Pancreatics + pan-creatin (8)	0.33	1.37	1.18	3.6	2.6 to 5.3

* Average includes only 13 cases.
† Average includes only 14 cases.

To the first two groups of patients the following generalization could be applied, with two excep-tions to be discussed later.

Patients without tryptic activity have their plasma glycine increased up to 2.5 times the fasting level (mean, 1.9 times) ; patients with good tryptic activity have their glycine increased by 2.6 to 7.6 times (mean, 5.0 times) 150 minutes after the test meal (Table I).

Similarly these patients could be divided into the same two groups by the rise in the plasma α -amino nitrogen in the 17 cases where this deter-mination was made (Table II). Seven patients given pancreatin (coated granules) with the gela-tin had their glycine and α -amino nitrogen toler-ance curves moved from the deficient to the high normal range. The results were similar whether gelatin was fed by mouth or introduced by tube directly into the stomach or duodenum.

Included in the group of 24 patients with no sig-nificant pancreatic enzymatic activity, were three patients showing rather high glycine responses, one so high on two of three occasions as to represent a striking exception. These patients all, inci-

dentally, had a diagnosis of meconium ileus at birth. The ratios of the plasma glycine levels after and before gelatin were: R. E., 2.5; M. M., 3.2; and D. B., 4.1, 5.7, and 3.0. The last patient had hepatic disease (probably homologous serum jaun-dice) more severe at the time of the first two tests than at the time of the third test. Since the plasma glycine level undoubtedly represents a balance be-tween the relative rates of the absorption and of the disposal of glycine, severe hepatic disease may be a complicating factor in this test.

The third group consisted of the six patients who presented relatively low yet quite definite tryptic activity in their duodenal contents. The ratio of final to original glycine levels were as fol-lows: D. R., 2.2; A. O., 2.4; S. F., 2.9; F. M., 3.2; R. V., 3.8; P. N., 5.7. Three of these values are above the range obtained for patients having no significant amount of tryptic activity. That a group of children showing intermediate degrees of pancreatic enzyme activity should range rather widely in their rates of gelatin digestion is not surprising. Heretofore partial pancreatic insuf-ficiency, in patients with the clinical appearance of pancreatic fibrosis, has not been described. This group is under study.

Finally, a single patient was observed who had normal enzymatic activities in his duodenal fluid, but who showed a rise to only 1.9 times his fast-ing plasma glycine after his test meal. This pa-tient could absorb glycine no better when pan-creatin was fed with the gelatin, or even when the glycine was fed *in the free state*. Since children with pancreatic disease absorbed glycine readily in either of the last two situations, clearly this is a different type of deficiency, and accordingly this patient is not included in the general averages.

TABLE II

The plasma α -amino nitrogen following gelatin feeding
The concentrations are in milligrams per 100 ml.

	Fasting		Increase				Ratio, higher level to fasting level	
			After 60 min.		After 150 min.			
	Mean	Range	Mean	Range	Mean	Range	Mean S.D.	Range
Controls (10)	3.55	2.90 to 4.54	2.31	0.60 to 4.48	3.51	1.49 to 6.22	2.0±0.3	1.43 to 2.50
Pancreatics (7)	3.38	2.89 to 4.05	0.32	-0.37 to 1.10	0.57	-0.78 to 1.35	1.2±0.2	0.93 to 1.40
Pancreatics + pan- creatin (6)	3.23	2.55 to 4.81	4.04	3.02 to 5.35	3.65	2.10 to 5.33	2.3±0.4	1.82 to 2.92

The subject also yielded a flat glucose tolerance curve.

Apparently a further test is desirable for an occasional patient to determine whether or not pancreatin intensifies significantly the elevation of the plasma glycine produced by gelatin feeding. Not only will this permit detection of the probably rare patient who cannot absorb readily even free glycine, but should also assist in clarifying the status of subjects who may show equivocal responses.

SUMMARY

1. Forty-nine patients presenting symptoms of malnutrition and respiratory disease suggesting a diagnosis of pancreatic fibrosis have been studied as to the response of their plasma glycine concentrations to the feeding of gelatin.

2. Twenty-two out of 24 patients having no significant tryptic activity in their duodenal fluid showed rises to not more than 2.5 times their fasting glycine levels. Nineteen patients having good pancreatic enzyme activity showed increases to more than 2.5 times the fasting value (average, five times fasting level). Liver disease may have been a factor in the exceptional increases shown by one of the patients with pancreatic disease.

3. The feeding of pancreatin with the gelatin changed the responses of either the glycine or α -

amino nitrogen from the pancreatic-deficient range to the high normal range.

4. A group of six patients showing definite, although small, tryptic activity in their duodenal fluids gave rather widely ranging responses to the test.

5. A single patient presenting evidence of normal secretion of pancreatic enzymes absorbed glycine poorly even when the amino acid was fed in the free state.

The assistance of Miss Jean Streicher is gratefully acknowledged.

STUDIES IN CIRRHOSIS OF THE LIVER. I. RELATIONSHIP BETWEEN PLASMA VOLUME, PLASMA PROTEIN CONCENTRATIONS AND TOTAL CIRCULATING PROTEINS

By GLENN I. HILLER, ELSTON R. HUFFMAN, AND STANLEY LEVEY

(From the Department of Medicine, the Wayne County General Hospital and Infirmary, Eloise, Michigan, and the Department of Physiological Chemistry, Wayne University College of Medicine, Detroit)

(Received for publication July 22, 1948)

INTRODUCTION

Addis, Poo and Lew (1) aptly demonstrated the importance of the liver as a storage place for protein substances. The extensive studies of Whipple and his associates (2, 3) allowed some insight into the magnitude of this protein storage and its availability during time of need. It also seems well established that the liver is the principal site of formation of albumin and fibrinogen and to a lesser extent of globulin (4-10). In the presence of severe hepatic disease such as advanced cirrhosis, the functions of protein synthesis and storage are presumably inhibited and this inhibition is reflected by alterations in the various protein concentrations in the plasma. Supporting this concept are the observations (4, 5) which correlated the fibrinogen content of the blood with the degree of liver injury. Similarly, hypoalbuminemia has been established as a characteristic laboratory finding in patients with far advanced cirrhosis of the liver (6, 7). Plasma protein concentrations cannot, however, be used as an index for total circulating proteins or plasma volume (11, 12). It has already been shown that the plasma volume may be elevated in patients with cirrhosis of the liver (13). In a previous communication (14), data were presented from patients with cirrhosis of the liver, illustrating normal values for total circulating proteins despite the presence of low protein concentrations in the serum. The purpose of this communication is to record further data concerned with the plasma volume and the quantitative estimation of the various plasma proteins in patients with far advanced Laennec's cirrhosis of the liver.

MATERIAL AND METHODS

Twelve patients were chosen for this study. At the onset of investigation each patient exhibited edema, ascites, anemia, hepatomegaly, spider angiomas, and

evidence of protein and multiple vitamin deficiency. Patients with jaundice were excluded from the study. Biopsy specimens from the liver, obtained by means of peritoneoscopy from 10 of the patients, were consistent with the impression of far advanced Laennec's cirrhosis. The presence of complicating disease was excluded by means of venous pressure determinations, circulation times, electrocardiograms, renal function tests and roentgenograms of the entire gastrointestinal tract and chest. All patients were men and ranged in age from 38 to 67 years. The average age for the entire group was 49.7 years.

Laboratory tests including hippuric acid excretion (intravenous procedure), bromsulphthalein excretion (5 mg. per kilogram of body weight), prothrombin time, cephalin-cholesterol flocculation and quantitative thymol turbidity were repeated at approximately biweekly intervals. As far as possible these laboratory procedures were obtained within 48 hours before plasma volumes and protein concentrations were determined.

Plasma volumes were determined in the fasting state at bed rest according to the method of Gibson and Evans (15) as modified by Gibson and Evelyn (16). Dye free samples of serum obtained before the injection of T-1824 were used as control readings. Fifteen minutes was found sufficient time to permit thorough mixing of the dye. Plasma volume was finally estimated by extrapolation of the time-concentration curve of the dye. Predicted plasma volumes were estimated according to height (17). Total blood volume was calculated from the simultaneous determination of the plasma volume and the venous hematocrit according to the formula (18):

$$\frac{\text{Plasma volume}}{100 - \text{hematocrit}} \times 100 = \text{blood volume.}$$

The venous hematocrit was determined according to the method of Wintrobe modified by the use of a 4 ml. capacity tube.

Total protein and albumin were determined according to the method of Howe (19) as modified by the use of Conway cells for the estimation of ammonia nitrogen (20). Fibrinogen was determined by conversion to fibrin (21) and, after digestion, the estimation of fibrin nitrogen by means of the Conway cell procedure. All blood samples for nitrogen determinations, hematocrits and plasma volumes were obtained simultaneously.

During the period of observation each patient was maintained on a daily diet in excess of 3000 calories,

120 or more grams of protein, moderately low in fat and containing approximately 2.7 grams of sodium chloride. Dietary therapy was augmented by vitamin supplements and, in some patients at the beginning of the study, by choline chloride and yeast. In a very few instances protein hydrolysates were given for a short period of time. For approximately the first half of the period of observation each patient received ammonium chloride, 6 grams daily for three days, followed by the administration of 2 ml. of mercupurin or mercurhydrin either intra-

venously or intramuscularly. After a three day rest period this procedure was repeated. For reasons to be discussed it was felt that diuresis in this manner did not appreciably influence the plasma volume. All patients were considered semi-ambulatory.

RESULTS

Persistently abnormal results for thymol turbidity, cephalin-cholesterol flocculation, hippuric

acid excretion and bromsulphthalein excretion were found in all patients throughout the study. Prothrombin time returned to normal in all patients soon after the institution of parenteral and oral vitamin K therapy. The results of these five tests were taken to indicate that persistent liver damage was present in each patient for the duration of the study.

Table I contains the correlated data obtained from observations on plasma volume, serum protein concentrations and total circulating proteins in the 12 patients. Percentage deviation values for the various serum protein concentrations were based on the minimum normal values of 6, 4 and 2 grams per 100 ml. for total protein, albumin and globulin respectively (22). The minimum normal values for the total circulating proteins in any given patient were obtained by use of these figures and the predicted plasma volume. Thus, any value for the individual total circulating proteins which exceeded the theoretical minimum normal value could be considered within normal limits for the patient.

It is apparent that the vast majority of the individual plasma volumes represent significant elevations above the predicted normal values. In 83 determinations, 68 (81.9 per cent) were more than 10 per cent above predicted values. Thirty (36.1 per cent) were more than 50 per cent above normal. In one patient (J. C.), nine of 12 determinations were more than 50 per cent above normal. Twelve determinations (14.4 per cent) were within plus-minus 10 per cent of predicted values. The three remaining determinations were more than 10 per cent below normal. Despite fluctuations, sustained elevations in plasma volume were present in most of the patients.

The total blood volume was estimated 79 times. Of these, 60 (75.9 per cent) were more than 10 per cent above predicted values. Eleven (13.9 per cent) were more than 50 per cent above normal. Of the remaining determinations, 14 (17.7 per cent) were considered to be within normal range and five (6.3 per cent) were more than 10 per cent below normal.

Total protein concentration in the serum was determined 84 times on the 12 patients. Of these, 34 (40.4 per cent) were below 6 grams per 100 ml. Three patients (A. B., C. P., E. D.), accounting for nine determinations, had total protein concen-

trations consistently above 6 grams per 100 ml. Thus, the remaining nine patients were considered to have had hypoproteinemia either consistently or at some time during the course of their study.

The quantity of total circulating protein was found to be within theoretical normal limits in 69 (86.2 per cent) of 80 determinations. Five patients (C. P., F. P., E. D., A. B., J. G.) had total circulating protein values consistently within the range of normal. These five patients accounted for 19 of the 80 determinations.

Albumin concentration in the serum was determined 82 times. Of these, 75 (91.4 per cent) were below 4 grams per 100 ml. Each patient exhibited hypoalbuminemia, as determined by concentration levels, almost consistently throughout his period of study. At no time did eight of the patients reach a normal value for albumin concentration.

The quantity of total circulating albumin was found to be within theoretical normal limits in 32 (41.0 per cent) of 78 determinations. Only one patient (J. G.) had consistently normal values. This patient accounted for six of the determinations.

Globulin concentration in the serum was determined 81 times. In only four instances was the globulin concentration below 2 grams per 100 ml. This represented 4.9 per cent of the total number of the determinations.

The quantity of total circulating globulin (77 determinations) was found to exceed the theoretical minimum normal values in every instance.

Fibrinogen concentration was determined 82 times. In 64 (78.0 per cent) the concentration was above 200 mg. per 100 ml. In 75 (94.9 per cent) of 79 determinations, the quantity of total circulating fibrinogen was found to be above the theoretical minimum normal values. One patient (J. C.), at a time when the plasma volume was 5080 ml., had a fibrinogen concentration of only 72.5 mg. per cent which represented a total circulating value of 3.6 grams. Another patient (H. R.) had moderately low values on two occasions; at one time the plasma volume was 2622 ml., the fibrinogen concentration 127 mg. per cent and the total circulating quantity of fibrinogen 3.3 grams. At another time the plasma volume was 2278 ml., the fibrinogen concentration 99.8 mg. per cent and the quantity of total circulating fibrinogen 2.2 grams. A third patient (A. D.) accounted for the

fourth subnormal value. The plasma volume was 4550 ml., the fibrinogen concentration 126 mg. per cent and the quantity of total circulating fibrinogen 5.7 grams. At no time did any of the patients exhibit hemorrhagic tendencies which could be attributed to subnormal values for fibrinogen.

From these observations it is apparent that the serum protein concentrations alone cannot be used to estimate the quantity of total circulating proteins in patients with advanced Laennec's cirrhosis of the liver. It is also apparent that any estimation of the degree of protein synthesis depends, in part, upon the determination of total circulating quantities rather than concentrations in the serum. Thus, patients with low concentrations of proteins in the plasma may, by virtue of sustained elevations in plasma volume, have total circulating quantities within the limits of normal. These data, based upon the total number of individual determinations, are summarized in Table II.

TABLE II

Tabular listing of the number of individual determinations on 12 patients with advanced Laennec's cirrhosis of the liver showing both numerical and percentile relationship between concentration of proteins and circulating proteins

	Number of determinations	Number of determinations above minimum normal value	Per cent of determinations above minimum normal value
Plasma volume	83	68*	81.9
Total protein concentration	84	50	59.6
Total circulating protein	80	69	86.2
Albumin concentration	82	7	8.6
Total circulating albumin	78	32	41.0
Globulin concentration	81	77	95.1
Total circulating globulin	77	77	100.0
Fibrinogen concentration	82	64	78.0
Total circulating fibrinogen	79	75	94.9

* Number of plasma volumes more than 10 per cent above predicted values.

Attempts to evaluate response to treatment were limited to seven patients all of whom were studied for more than 90 days. Since results of the four hepatic function tests discussed above could not be correlated with the clinical state of the patient, clinical improvement was based specifically upon disappearance of edema and ascites, return to a clinically normal nutritional state, improved or normal blood count and, finally, ability to remain ambulatory without recurrence of preexisting signs and symptoms. The maintenance of a continued state of improvement while fully ambulatory out-

side the hospital was considered an important factor in evaluating prognosis.

Only three patients (J. C., J. G., C. W.) satisfied these criteria for improvement. The first two patients have been observed for four months following discharge from the hospital. The third (C. W.) has remained as a hospital employee. A fourth patient (F. P.), in whom temporary improvement occurred, failed towards the end of the study. Coincident with this failure to maintain an improved state was the demonstration of a filling defect in the stomach. Ability to maintain a quantity of total circulating albumin above predicted minimum values occurred in three of these patients and temporarily in the fourth (F. P.) despite the presence of hypoalbuminemia as estimated by concentrations in the serum. Another patient (J. R.) showed only moderate improvement while in the hospital and has not been adequately followed since discharge. One (G. O.) has shown no improvement over a long period of time and one (T. M.) expired from his disease and complicating bronchopneumonia. These last three patients were not able to maintain a quantity of total circulating albumin above predicted minimum values.

Of the remaining five patients, all of whom were studied for less than 90 days, only two (E. D., C. P.) are making satisfactory progress. One (A. B.) left the hospital before response to treatment could be evaluated. Another (H. R.) expired in severe hepatic decompensation complicated by bronchopneumonia. The fifth (A. D.) expired following a "button" operation performed in another hospital without our knowledge. This patient had entered the hospital with a history of having had 96 abdominal paracenteses during the preceding 12 months. Routine studies revealed the presence of peritoneal tuberculosis complicating the cirrhosis. Despite this complication and the loss of large amounts of albumin in the ascitic fluid, a near normal quantity of total circulating albumin was maintained in the plasma until his demise.

Although this series is small, clinical improvement, based on criteria given above, could be correlated with ability to maintain a quantity of total circulating albumin above predicted minimum values. Since all of the patients exhibited subnormal concentrations of albumin in the serum, this correlation existed only in those who had sustained

TABLE III

elevations in plasma volume. In most instances wide fluctuations in serum protein concentrations were not present. Three of the four patients who made the greatest degree of improvement possessed high plasma volumes and quantities of total circulating albumin above predicted minimum values throughout most of the study. The fourth patient (C. W.) eventually became able to maintain a normal quantity of total circulating albumin without an appreciable elevation in plasma volume.

Observations relative to the average percentile deviation from the predicted plasma volume and from the minimum normal values for both concentrations and total circulating proteins for each patient are presented in Table III. In most instances fluctuations in plasma volume in any given patient were paralleled by similar fluctuations in the quantity of total circulating protein. This observation is illustrated in Figure 1 which records the data on one of the patients.

DISCUSSION

The sustained elevations in plasma volume in cirrhotic patients cannot be explained by behavior of the dye. Wide variations in protein concentration do not appreciably affect the optical density of T-1824 (23). In accord with reports elsewhere (13, 24), we were unable to demonstrate the presence of the dye in the ascitic fluid as long as one hour after the intravenous injection of large amounts. On the basis that intra-abdominal pressure might act as a barrier preventing diffusion of the dye into the peritoneal cavity, the ascitic fluid was largely removed. Again, the dye failed to appear in the remaining ascitic fluid as long as one hour later under similar conditions. Under cer-

FIG. 1

Predicted normal values for patient G. O. are: Plasma volume, 2750 ml.; total circulating protein, 165 grams; total circulating albumin, 110 grams; total circulating globulin, 55 grams; total circulating fibrinogen, 5.5 grams.

tain circumstances, however, the dye may appear in the ascitic fluid. One patient developed a distinct blue color in the ascitic fluid after a large number of plasma volume determinations were made with T-1824 in a relatively short period of time. Inspection of the time-concentration curves did not reveal any sudden or unexpected loss of dye from the vascular system in any of the patients. It is undisputed that dye eventually escapes into the interstitial fluid and certainly into the ascitic fluid, but not appreciably so during the time required to perform the plasma volume determination.

Other factors in the cirrhotic patient may contribute to the elevated plasma volume. Hydræmic hypovolemia in the severe stages of pernicious anemia and increases in plasma volume in the hypochromic anemias have been reported elsewhere (25). In nearly all instances the patients reported here exhibited at least moderate degrees of anemia and reduced hematocrit values at some time during the course of their study. Inability of the cirrhotic liver to normally inactivate the posterior pituitary antidiuretic factor (26) and to normally inactivate and conjugate estrogens undoubtedly contributes to the elevated plasma volume in certain instances. The relation of the normal and pathologic liver to estrogen metabolism has recently been reviewed (27). The water-retaining effect of estrogens (28) is now well known. The urine of cirrhotic patients with edema has been found to contain a potent antidiuretic factor (29). Recently, a vasodepressor substance (VDM) of hepatic origin has been shown to appear in the blood of decompensated cirrhotic patients (30). Still more recently, it has been shown that cirrhotics with edema release only very small amounts of sodium into the urine (31). Lastly, it has been suggested that the chief factors responsible for the elevated plasma volume are distension behind the point of portal obstruction and the increased size of the collateral vascular bed required to handle the portal circulation (13).

Reference to the plasma volumes in any given patient in this series reveals no significant or consistent correlation with the presence or absence of anemia, edema or ascites. In the four patients in whom edema and ascites disappeared and, clinically, the nutritional state returned to normal, the plasma volumes remained elevated. Three of

these improved patients had unusually high plasma volumes which were sustained throughout the study. Such elevations, in the absence of edema, cannot be explained on the basis of sodium retention, hypoproteinemia or disturbed estrogen metabolism. Since the plasma volume tends to increase in anemic states, anemia probably was a contributing factor in most of these patients. The presence of antidiuretic factors was not investigated but also would seem unlikely as a major cause of the elevation in the absence of edema. The patients reported here exhibited evidence of collateral circulation manifested by hemorrhoids, dilated superficial abdominal veins and esophageal varices. All had large livers and two had large spleens. Since the large liver and extensive collateral vascular bed must add a considerable increment to the capacity of the vascular system, it is suggested that a large portion of the sustained elevation in plasma volume in advanced Laennec's cirrhosis has its basis in this explanation.

Most of these patients received a mercurial diuretic and ammonium chloride at regular intervals during the first half of the study. Although small fluctuations in plasma volume occur during active diuresis, this is a temporary phenomenon and does not influence the sustained increase. Furthermore, inspection of plasma volume curves for each patient before and after diuresis revealed no significant alterations which could be attributed to the use of diuretics.

In some of the patients changes in plasma volume, at a time when hematocrits remained relatively constant, indicated tremendous increases in circulating red cell mass. In this respect it should be emphasized that determination of the circulating red cell mass by means of the plasma volume and hematocrit affords only a rough estimate. A macrocytic anemia was present at one time or another in all of the patients but not consistently so. Bone marrow studies were not obtained on these patients; however, other studies have indicated that increased erythropoiesis is frequently present in cirrhosis of the liver. Berman *et al.* (32) reports the consistent change in the bone marrow to be extension of the marrow organ so that active hematopoiesis is found in the shafts of long bones. The bone marrow is of normal or increased cellularity, with normal or increased erythrocytogenesis, regardless of the presence or absence of anemia.

Hypocellularity of the marrow was considered an unusual finding.

The clinical significance of the serum protein changes has been recently reviewed (33). Concentrations of proteins in the serum cannot, however, be used to estimate total circulating quantities in cirrhotic patients. This is emphasized by the sustained elevations in plasma volumes in the patients reported here. That the quantity of total circulating albumin may be related to prognosis is demonstrated by the findings in four of the patients who improved according to criteria already discussed. Despite low concentrations of albumin in the serum and persistently abnormal hepatic function tests, three of these patients have shown continued improvement and ability to maintain a quantity of total circulating albumin above the theoretical minimum values. The same correlation existed temporarily in a fourth patient. Two of these patients have been under observation for more than 16 months and two for more than nine months. No correlation existed between improvement and the various serum protein concentrations, total circulating protein, total circulating globulin and several hepatic function tests. Observations (34) on the amount of protein lost in the ascitic fluid due to repeated abdominal paracenteses in some of the patients suggested that synthesis of albumin 'proceeded at an unusually high rate despite low concentrations in the serum and impairment of other liver functions.

Ability to synthesize fibrinogen in normal quantities even in the presence of advanced cirrhosis is also suggested. Apparently, fibrinogen synthesis is one of the last functions to be impaired in progressive cirrhosis of the liver.

SUMMARY

1. Periodic observations of the plasma volume, blood volume, various serum protein concentrations and total circulating proteins were made on 12 patients with far advanced Laennec's cirrhosis of the liver.

2. Considerable and sustained elevation of the plasma volume was present in most of the patients. Observations on four patients, during the absence of clinical edema and ascites, suggest that the major portion of the elevation in plasma volume is due to hepatomegaly, splenomegaly and the ex-

tensive collateral circulation which develops in certain patients with cirrhosis of the liver.

3. Subnormal concentrations of proteins in the serum did not necessarily indicate subnormal quantities of total circulating proteins.

4. Clinical improvement was correlated with ability to maintain a normal quantity of total circulating albumin in four of the patients. It is suggested that this may be an important factor in determining prognosis in the cirrhotic patient.

5. It is possible for patients with advanced cirrhosis of the liver to show clinical improvement for long periods of time despite persistent impairment of liver function as determined by several hepatic function tests and despite the presence of subnormal concentrations of albumin in the serum.

ACKNOWLEDGMENT

Appreciation is expressed to Mrs. Dorothy L. Dezelia, R.T., for technical help in carrying out this study.

THE AGGLUTINATION OF AUTOCLAVED HEMOLYTIC STREPTOCOCCI BY SERUM FROM PATIENTS WITH RHEUMATIC FEVER AND OTHER CONDITIONS¹

By SUNG J. LIAO²

(From the Section of Preventive Medicine, Yale University School of Medicine, New Haven)

(Received for publication September 20, 1948)

Thulin (1-3) has recently reported an agglutination test, using human serum and hemolytic streptococci which had been treated at a high temperature. He found that in human sera the agglutination titers were significantly higher in samples from patients with rheumatic fever and with rheumatoid arthritis than in others and that the titers observed in both diseases were similar. This test would seem to offer an unusually simple technique for the measurement of antibodies which occur in active streptococcal diseases and in rheumatoid arthritis. Many streptococcal agglutination tests have been described and proposed in the past, but the principle of subjecting the bacterial suspension to a temperature of 120° C prior to its use as an agglutinin (4), is a new suggestion insofar as its clinical application for the study of streptococcal diseases is concerned; for this reason alone it has seemed to deserve further investigation.

It is the purpose of this paper therefore to report confirmation of Thulin's observation that sera from patients with rheumatic fever and rheumatoid arthritis agglutinate autoclaved streptococci and to present the results of further investigations utilizing this technique.

MATERIALS AND METHODS

1) *Preparation of bacterial suspension.* The hemolytic streptococcus³ used throughout the present work was a strain of Group A Type 4. Cultures were made with beef heart infusion broth containing either 0.5% calf serum or 1% glucose; after incubation at 37° C for 15 to 18 hours, the bacterial cells were collected by centrifugation and washed once with phosphate buffer solution (0.01 M) at pH 7.8. The cells were then resuspended in the buffer and autoclaved at a temperature of

120° C for two hours. The heat-treated cells were then washed twice with the buffer (pH 7.8). Finally, a heavy suspension of the autoclaved bacteria was made in a small volume of physiological saline, buffered with 0.01 M phosphate to pH 7. Tests done with unbuffered saline prepared from laboratory-distilled water, which was found to have a pH of about 5 to 6, gave non-specific agglutination.

For the agglutination test, the bacterial suspension was diluted to a concentration of about 100 million organisms per milliliter by comparison with a barium sulphate standard, containing a third of the strength of the No. 1 tube of the Brown's standard (5, 6). The undiluted bacterial suspension was usually not kept longer than one week in the refrigerator at a temperature of 4° C. Diluted suspensions were freshly made for each test from the stock.

2) *Serum.* Samples of serum were obtained from patients suffering from rheumatic fever of varying severity and at different stages of their illness; from patients with scarlet fever or other bacteriologically proven streptococcal diseases taken during active and convalescent stages of their illness; from patients affected by rheumatoid arthritis, taken at various stages of the disease; from individuals with a wide variety of ailments other than the above three; and from "normal" subjects.⁴ All the samples of serum were stored at -17° C and were not heated before being tested.

3) *The agglutination technique.* Serial two-fold dilutions of serum were made with buffered saline (pH 7), starting from 1:20. To 0.2 ml of serum dilution in each tube an equal volume of the bacterial suspension was added. Therefore, the final dilutions of each serum tested ranged from 1:40.

After the addition of the cells to the serum, the tubes were shaken, incubated in a 52° C waterbath for two hours and left in the refrigerator at 4° C for a period of 15 to 18 hours. A longer time in the refrigerator tended to give rise to excessively high titers, while too short a period resulted in low titers. When the test was read, the individual tubes were gently shaken and then read

¹ Aided by a grant from the Life Insurance Medical Research Fund.

² Milbank Memorial Fund Fellow.

³ The term "hemolytic streptococcus" throughout this paper refers to the Lancefield Group A beta-hemolytic streptococcus, unless stated otherwise.

⁴ The serum samples were collected and generously made available by Dr. Robert W. Quinn from the patients in the Grace-New Haven Community Hospital and Dispensary Clinics, New Haven, Conn., the U. S. Naval Hospital, St. Albans, L. I., St. Francis Sanatorium for Cardiac Children, Roselyn, L. I., the Children's Center, New Haven, Conn., and Southbury Training Center, Southbury, Conn.

against a black background, without the aid of a hand lens. The presence of sandy granules which were not broken into a homogeneous suspension by the shaking was considered as definite agglutination. The final dilution of the serum in the last tube of the series which showed definite agglutination was taken as the agglutination titer of the sample.

4) *Calculations.* In this agglutination test, two-fold dilutions of serum were used and the final dilution of

serum was adopted for the agglutination titer of the sample. This serial two-fold dilution of serum forms a geometric series with a common ratio of 1:2. To obtain a geometric mean from numericals of the dilutions is not too easy a job. If it could be converted into an arithmetic series, the task would then not be difficult. The series of dilutions of serum starts with 1:40. Here $40 = 20 \times 2^1$. The next tube contains a dilution of 1:80, where $80 = 20 \times 2^2$. The third tube contains a

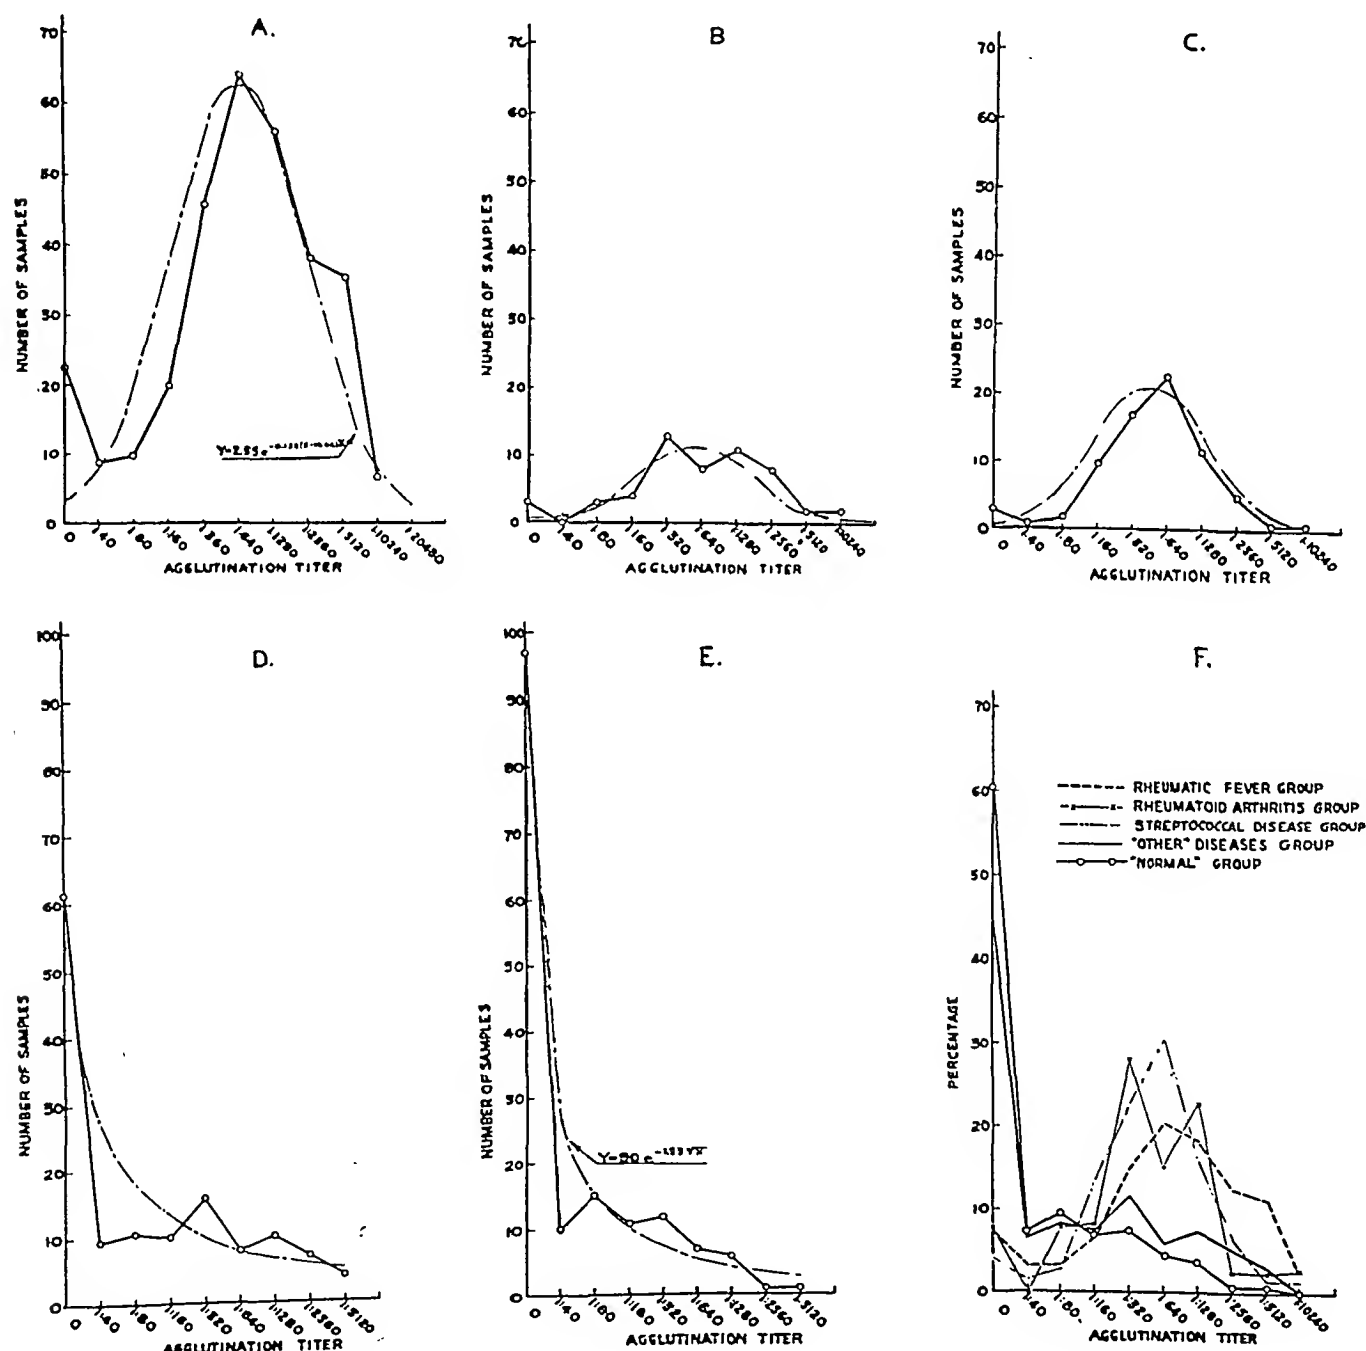

FIG. 1. DISTRIBUTION OF AGGLUTINATION TITERS OF THE FIVE GROUPS OF HUMAN SERUM

 B. Serum from patients with rheumatoid arthritis. (50 samples, mean titer 1:614.)
 C. Serum from patients with "streptococcal diseases." (75 samples, mean titer 1:474.)
 D. Serum from patients with "other" diseases. (137 samples, mean titer 1:95.)
 E. Serum from "normal" subjects. (160 samples, mean titer 1:49.)
 F. Percentage distribution of the five groups.

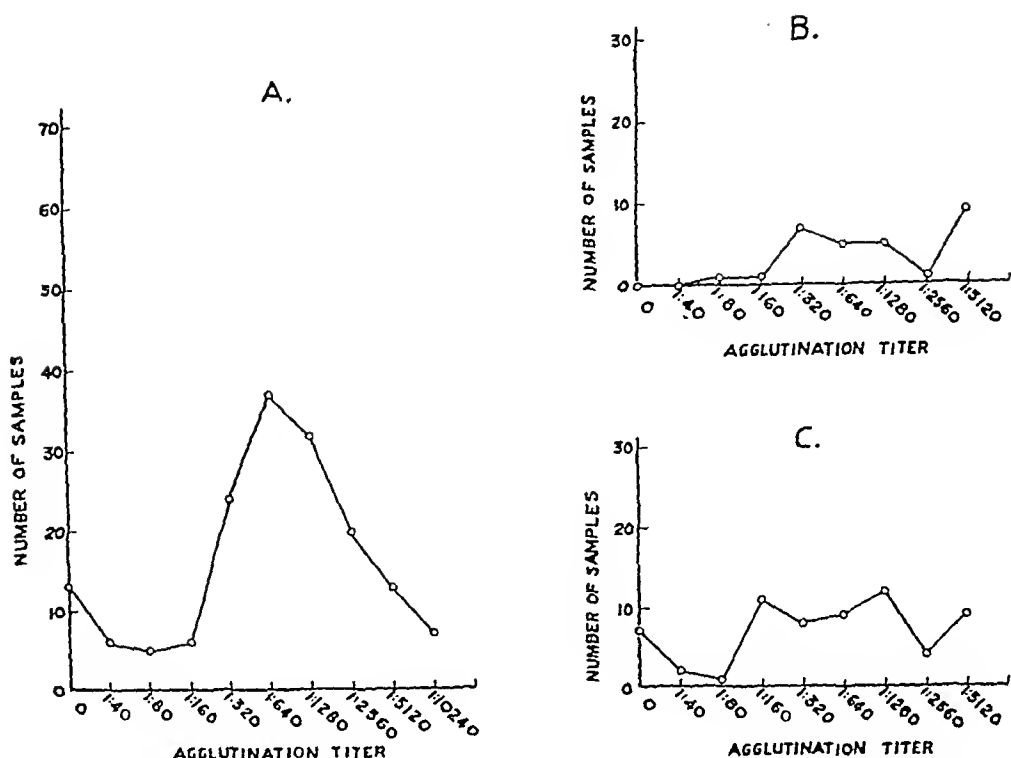

FIG. 2. FREQUENCY DISTRIBUTION OF AGGLUTINATION TITERS OF SERUM FROM RHEUMATIC FEVER PATIENTS

- A. Active. (163 samples, mean titer 1:640.)
 B. Active subsiding. (29 samples, mean titer 1:1084.)
 C. Inactive. (63 samples, mean titer 1:456.)

dilution of 1:160, where $160 = 20 \times 2^2$. And so on. The ninth tube contains a dilution of 1:10240, where $10240 = 20 \times 2^9$. This series may, then, be coded with the first tube (1:40) as 1, second tube (1:80) as 2, . . . the ninth tube (1:10240) as 9, and with a negative reaction as 0 (Table I). Thus, the mean, the standard deviation, and the standard error of a group of serum may be calculated as usual. The *t*-test is used to compare the differences between two groups.

For converting the code of the mean into the original series, the following procedure may be taken. Taking the first group of serum as an example, the mean was calculated to be 5.01 in terms of the code. 5.01 lies between 5 and 6. 5 corresponds to $1:20 \times 2^5$. 5.01 should correspond to $1:20 \times 2^{5.01}$, or 1:645.

RESULTS

The first group consisted of 311 samples of serum obtained from 193 patients with rheumatic fever representing wide variations in severity and duration of activity of the disease. Only 23 of the 311 (7.4%) failed to show any agglutination (negative), and 269 (86.5%) showed agglutination

titers of 1:160 or higher. The geometric mean titer of the group as a whole was 1:645 (or 5.01, in terms of the code, with a standard deviation of 2.26 and standard error of 0.128) (Figure 1-A).

Sera from some of the rheumatic fever patients were further studied to determine the relation of the agglutination titer to the stage of the illness. Of the 311 samples of sera (charted in Figure 1-A), 49 were obtained from rheumatic fever patients whose detailed histories were not definitely known. Since the stage of their disease could not be determined accurately they were excluded from this analysis. One hundred and sixty-three samples were taken during the active phase of their illness and of these, 13 (8%) were negative and 139 (85.3%) had a titer of 1:160 or higher, with a mean agglutination titer of 1:640 (or 5.0, in terms of the code, with a standard deviation of 2.29 and a standard error of 0.182). It is noteworthy that the specimens of serum from ten of the 13 negative reactors were obtained within one week of the onset of their disease (Figure 2-A).

Twenty-nine samples were obtained from rheumatic fever patients when the activity of the disease was considered to be subsiding. None of these was negative and the agglutination titer of 28 samples was 1:160 or higher, with a mean titer of 1:1084 (or 5.76, in terms of the code, with a standard deviation of 3.01 and standard error of 0.558) (Figure 2-B).

Of 63 specimens of sera obtained from rheumatic fever patients during the inactive phase of their illness; seven (11.1%) were negative and 53 (84.2%) had a titer of 1:160 or higher with a mean titer of 1:456 (or 4.51, in terms of the code,

FIG. 3. COMPARISON OF MEAN AGGLUTINATION TITERS OF RHEUMATIC FEVER PATIENTS AT VARIOUS AGES WITH THOSE OF "NORMALS" OF THE SAMPLE AGE GROUP

In the top graph, the dotted line and crosses represent the distribution of mean agglutination titers of the rheumatic fever group at various ages; and the horizontal broken line, the grand mean titer of the rheumatic fever group (1:596 for a total of 266 samples).

In the lower graph, the lines and crosses represent the distribution of mean agglutination titers of the "normal" group at various ages; and the horizontal broken line, the grand mean titer of the "normal" group (1:56 for a total of 97 samples).

The numerals at each point indicate the number of samples examined at that particular age group.

FIG. 4. PERCENTAGE DISTRIBUTION OF AGGLUTINATION TITERS OF SERUM FROM RHEUMATIC FEVER PATIENTS AND FROM "NORMAL" SUBJECTS OF AGES BETWEEN FIVE AND 40

The circles represent rheumatic fever patients; the crosses, "normal" subjects.

with a standard deviation of 2.42, and a standard error of 0.305) (Figure 2-C).

There were seven samples of serum from patients with a diagnosis of possible rheumatic fever; and of these one was negative, and six had titer above 1:160. The mean agglutination titer was 1:640 (or 5.0 in terms of the code, with a standard deviation of 1.73, and standard error of 0.655).

From our data, the ages of 268 rheumatic fever patients were definitely known. Of these, 266 fell between the ages of five and 40. The mean agglutination titers of serum samples grouped in five-year periods were computed. The mean agglutination titer of the whole group was estimated to be 1:596. Of the same age group (five to 40), 97 samples from normal controls were recorded. They were analyzed in the same manner. The

mean agglutination titer of this group was 1:56. The difference between the mean agglutination titers of these two groups of population at the same ages was statistically significant (Figure 3). The percentage distributions of agglutination titers of these two groups were essentially the same as the original corresponding group (Figure 4).

Serial bleedings of three or more samples from each individual were obtained from 32 patients of the rheumatic fever group; they represented periods of observation varying from 21 to 245 days. In general, the agglutination reaction was negative in the first few days after the onset of the acute ill-

ness; thereafter the titer rose fairly rapidly to a level of 1:320 or higher during the active stage; and during the convalescent phases, it usually remained at this high level. In the few instances when the agglutination titer fell, the level, nevertheless, remained much higher than the mean titers of the control groups. Readings from three representative patients are shown in Figure 5.

Of the *second* group, comprising 50 samples of sera from 38 patients suffering from rheumatoid arthritis, three (6%) were negative and 44 (88%) had titers of 1:160 or higher. The mean titer for the group was 1:614 (or 4.76 in terms of the code,

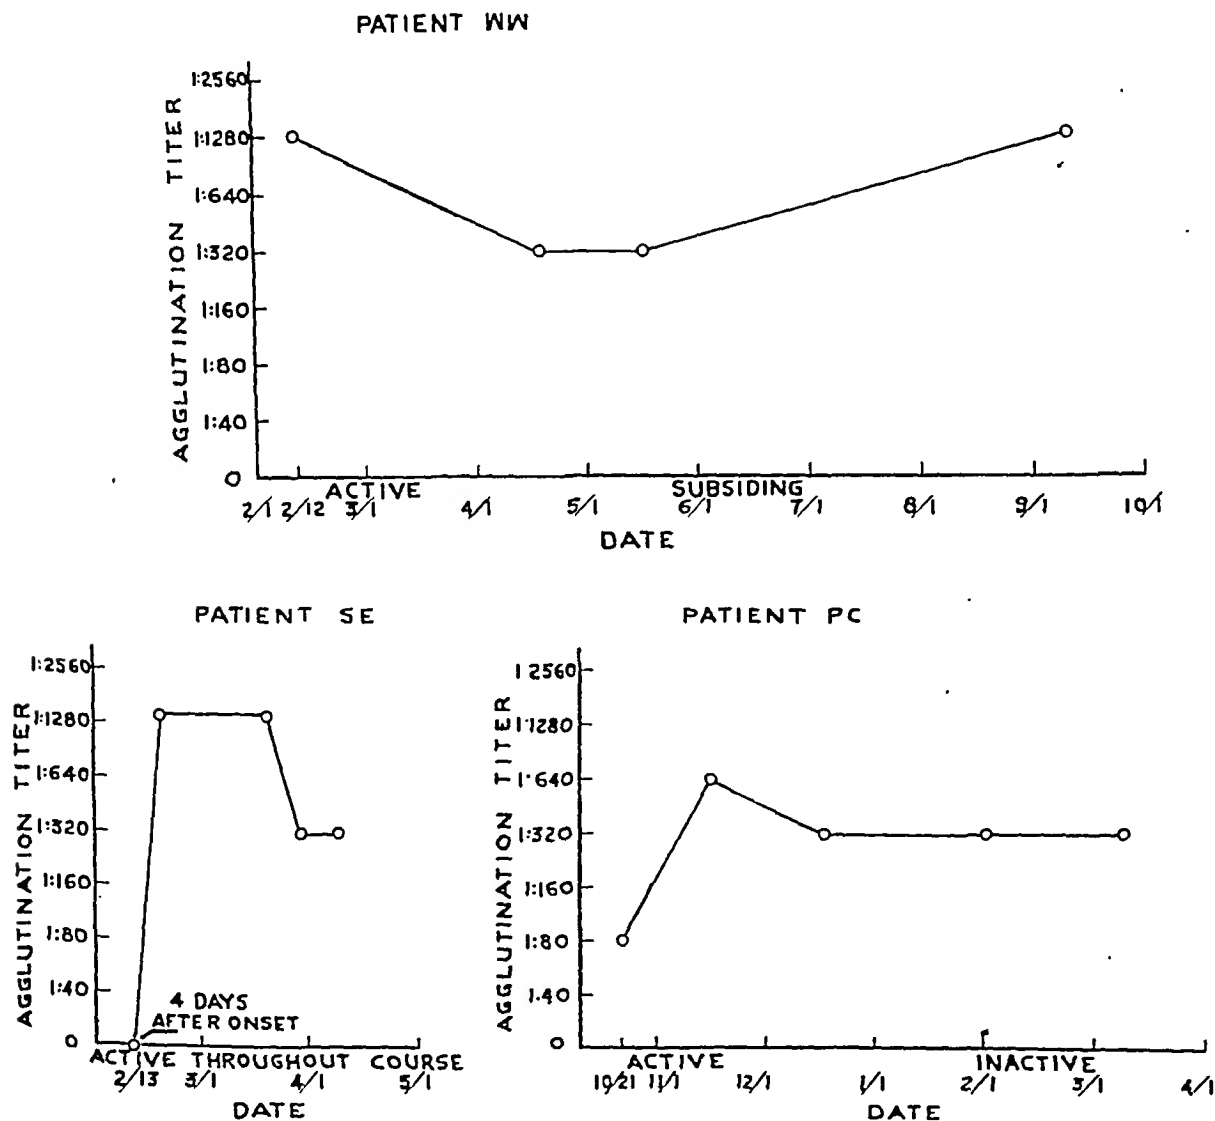

FIG. 5. THE AGGLUTINATION TITER OF SERUM FROM THREE PATIENTS WITH RHEUMATIC FEVER AS CORRELATED TO THE CLINICAL COURSE OF THE DISEASE

TABLE I

The distribution of the agglutination titers of the five groups of serum examined

with a standard deviation of 1.68 and standard error of 0.194) (Figure 1-B).

The *third* group of sera comprised 75 samples from 65 patients who were either in the active or convalescent stage of scarlet fever or other bacteriologically proven streptococcal infections. Three (4%) of the 75 samples collected were negative and 69 (92%) showed a titer of 1:160 or over, with a mean titer of 1:472 for this group (or 4.56 in terms of the code, with a standard deviation of 1.68 and standard error of 0.194) (Figure 1-C).

The *fourth* group (one of the two control groups) of sera included 137 specimens of serum obtained from 133 patients in the Grace-New Haven Community Hospital with infectious and non-infectious diseases other than those given above. Of the 137 sera in this group, 61 (44.5%) gave negative results and 55 (40.2%) had an agglutination titer of 1:160 or higher. The mean agglutination titer was 1:95 (or 2.24 in terms of the code, with a standard deviation of 2.53 and a standard error of 0.216) (Figure 1-D).

In this fourth group, 11 patients suffering from lobar pneumonia were also included. The sera of nine of them gave negative results and two demonstrated an agglutination titer of 1:80 with a mean titer of 1:17. This fourth group also included 14 patients with tonsillitis in whom definite bacteriological proof for hemolytic streptococcus as the causative organism was lacking. Among these 14 the sera of three gave a negative reaction, while

those of ten gave agglutination titers of 1:160 or higher. The mean titer of the 14 was 1:290 (or 3.86 in terms of the code, with a standard deviation of 2.50 and standard error of 0.664). After the exclusion of these 14 patients, the mean agglutination titer of the fourth group became 1:83 (or 2.06, with a standard deviation of 2.48 and a standard error of 0.223).

The *fifth* group (the other control group) comprised sera from "normal" subjects, and included apparently healthy subjects, surgical patients such as those with simple fractures or hernias, and those admitted for routine tonsillectomy and adenoidectomy. From 142 "normal"⁵ subjects, 160 samples of sera were obtained. Of the 160, 97 (60.6%) were negative and 38 (23.8%) showed a titer of 1:160 or higher. The mean agglutination titer for the group was 1:49 (or 1.29, in terms of the code, with a standard deviation of 1.94 and standard error of 0.153) (Figure 1-E).

A comparison was made of the above five groups with regard to the percentage distributions of their agglutination titers. This is illustrated in Figure 1-F.

No special effort was made to determine the experimental error of this particular agglutination test. However, from repeated tests on 25 samples of serum (two tests on each sample at differ-

⁵ The word "normal" is used in this paper for convenience as the designation for this heterogeneous group of subjects who were apparently healthy or had no obvious infectious diseases.

ent times and with different preparations of the bacterial suspension), the mean difference of agglutination titers was found to be less than two-fold. Therefore, a four-fold difference of the agglutination titers may be considered significant.

DISCUSSION

Significance of finding. From the observations made, there was no statistically significant difference of the mean agglutination titers among the first three groups, viz., rheumatic fever, rheumatoid arthritis and streptococcal diseases. The differences between the mean titers of each of these three groups and the fourth (or patients suffering from diseases other than the above three) were highly significant statistically. Likewise, the differences between the mean titers of each of the above first three and the last group (composing "normal" subjects) also were significant. Though a statistically significant difference between the two control groups (*i.e.*, the fourth and the fifth) was demonstrated, this might be explained by the inclusion of patients suffering from tonsillitis and other similar conditions where definite bacteriological proof of causation by the hemolytic streptococcus was not obtained. The agglutination titers of the sera of these tonsillitis patients were, on the average, higher than those of the sera of other patients. The result of the fourth group as a whole might thus be influenced to some extent. However, the exclusion of these 14 patients did not significantly alter the mean agglutination titer of the fourth group. The differences between the fourth group after exclusion of these patients and the fifth group remained still significant. Among other causes, it is conceivable that an anamnestic reaction caused by the present illness on previous experiences with the streptococcus, known or unknown, might also contribute to the slightly higher mean titer of the fourth group. Therefore, this difference between the two control groups might not be taken too seriously. The frequency distribution curves of the agglutination titers of these two control groups were essentially the same (Figure 1, D and E). Those of the first three groups followed the pattern of the normal distribution curve (Figure 1).

Because the mean agglutination titers of the control groups were below 1:100, and those of the three test groups were above 1:320, it has seemed

reasonable to set the tentative line of demarcation between the control and the test groups at the level of 1:160. Therefore, if this test is to be used for clinical diagnostic purposes and when rheumatic fever is suspected, an agglutination titer of the patient's serum against autoclaved hemolytic streptococcus above 1:160 may be considered suggestive. From the estimation made by means of an empirical equation, $y = 2.55 e^{-0.128 x (x-10.02)}$ which was constructed from the data of the rheumatic fever group, the chances that the serum sample from a rheumatic fever patient would show an agglutination titer of, or over, 1:160 were 85 times out of 100. For the serum of a "normal" subject, the chances of being so were only about 20 times out of 100, as estimated from an empirical equation, $y = 90 e^{-1.25 \sqrt{x}}$ which was computed from our data. The estimate for the latter group was inevitably rather high, perhaps because the frequent occurrence of unrecognized infections of hemolytic streptococcus may give rise to an increased antibody titer. In the rheumatic fever group, a negative agglutination reaction, or a positive one with a low titer, might be explained by the fact that, at very early stages of the disease, the individual might not have elaborated enough antibodies against the "infection" to give a positive reaction with a high titer above the normal level. Moreover, there are always individual variations in the reaction to any antigenic stimulation. It is not to be expected, therefore, to observe a uniform narrow range of antibody titer. As is well known, for example, in the production of diphtheria antitoxin some horses are encountered which are refractory to diphtheria toxin or toxoid.

Rheumatic fever. Since rheumatic fever is mainly a disease of younger age groups, the question may be raised as to whether the age distribution of the rheumatic fever patients was sufficiently different from the control groups as to make a comparison impossible. As shown in Figure 3, the differences between the mean agglutination titers of the serum of these two groups of population at the same ages were statistically significant. Furthermore, the percentage distribution of agglutination titers of these two groups did not differ from their original corresponding groups. This serves as additional evidence that the agglutination titers were higher in rheumatic fever patients than in "normal" subjects.

From the studies on serial samples taken from patients at various stages of rheumatic fever, a negative reaction was observed with sera obtained within a week of the onset of the disease and the agglutination titer subsequently rose fairly rapidly and thereafter remained elevated. Thulin (3) attributed this agglutination reaction to an "O antigen" in the hemolytic streptococci. He also observed that "the O agglutinins are acute antibodies which, as a rule, make their appearance in seven to 14 days after the onset," and "in chronic cases, . . . the O agglutinins remain relatively unchanged." A negative reaction, therefore, does not exclude the presence of rheumatic fever particularly in the early stages, but a rise of the titer during the course of the disease is very suggestive. Repeated determinations at weekly intervals would appear to be indicated when the test is used as an aid in diagnosis. The degree to which sustained elevation of streptococcal agglutinins are maintained in rheumatic fever in possible contrast to the response in acute streptococcal disease is as yet unknown.

Rheumatoid arthritis. Extensive work has been done on agglutination reactions against hemolytic streptococcus with sera from patients suffering from rheumatoid arthritis. However, not many of the previous studies included numerous samples of sera from patients with rheumatic fever. The majority of them have shown higher values for rheumatoid arthritis and thus constituted a differential test between rheumatoid arthritis and rheumatic fever. The bacterial suspensions employed were either live cultures of streptococci or streptococcal suspensions killed at 56° C. Because the methods used were so different, a comparison of the data of previous studies with the results of the present work cannot easily be made. Although Clawson *et al.* (7) and Goldie (8, 9) demonstrated no difference of agglutination titers between sera from rheumatoid arthritis and rheumatic fever patients, the bacterial suspensions used by the two groups of workers were different. The size of the population examined and the stage of disease when the samples were collected are among the important factors which contribute to the variations in antibody titer, as demonstrated by different investigators. Using autoclaved hemolytic streptococci, Thulin obtained higher agglutination titers in rheumatoid arthritis and rheumatic fever patients

than in controls. In the series published in 1947 by him (2) 34 out of 43 of the "chronic polyarthritis" group showed agglutination titers of 1:160 or higher and none was negative. Of the rheumatic fever group, 13 of 16 showed agglutination titers of 1:160 or higher and none was negative; and of the control group, 114 of 117 were negative while not a single sample had a titer of 1:160 or higher. The following information was given in his latest monograph (3): 54 patients with rheumatic fever were examined by him within three to six months after onset; 51.9% of them showed an agglutination titer of 1:160 or higher. Over half of each of 20 scarlet fever patients and of 20 patients with acute tonsillitis had agglutination titers of 1:160 or higher. Of 285 patients with rheumatoid arthritis, 51.6% gave titers of 1:160 or higher. Only 7.6% of the control serum showed agglutination titers of 1:40 or higher. Our observations, as noted above, agree well to these points.

From the present study, this agglutination test could not differentiate rheumatic fever from rheumatoid arthritis. Since the number of series of bleedings at various stages of illness obtained from patients suffering from rheumatoid arthritis was not large, it is rather difficult to make definite comment on the usefulness of the test in diagnosis. This awaits the results of further investigation. Nevertheless, from our limited data, it appeared worthwhile to use this test in patients with rheumatoid arthritis as in cases of rheumatic fever.

The similarly high agglutination titers of the sera from patients with rheumatic fever and from those with hemolytic streptococcus has pointed to a possible etiological association of hemolytic streptococcus with rheumatic fever. On the other hand, one might take this finding as analogous to the Weil-Felix reaction in rickettsial diseases. This seems less likely in view of the epidemiological evidence of an association between streptococcal infections and rheumatic fever. Whether a similar interpretation can be applied to rheumatoid arthritis is beyond the scope of the present study. One may still wonder whether similarly high agglutination titers would be obtained with other autoclaved organisms, particularly other Gram positive or negative cocci. As mentioned above in the fourth group of sera examined, nine out of 11 samples of serum obtained from patients

with lobar pneumonia failed to agglutinate the autoclaved streptococci. This offered evidence for the specificity of this particular agglutination reaction. The denaturation of protein by heat has probably left the somatic polysaccharide alone among the known factors to be considered of any consequence in serving as the antigenic fraction responsible for the agglutination reaction. Further studies on the specificity of this reaction and the possible part played by the group-specific polysaccharide have been reported elsewhere (10).

SUMMARY

An agglutination reaction using autoclaved (120° C for two hours) hemolytic streptococci has been described and investigated. It has been used in this study with samples of serum from patients with rheumatic fever, rheumatoid arthritis, and streptococcal diseases, as well as with other conditions.

The agglutination titers in groups of patients with rheumatic fever, rheumatoid arthritis, and streptococcal diseases did not differ significantly one from the other. The titers in each of these conditions were significantly higher than in the control groups.

ACKNOWLEDGMENTS

Thanks must be due to Dr. Robert W. Quinn, who kindly provided the human sera used in this investigation, and to Dr. Edward C. Curnen, Jr., for his invaluable criticisms about this study. The writer wishes also to express his gratitude particularly to Prof. John R.

Paul for his guidance and counsel in the present investigation.

THE CLOTTING BEHAVIOR OF HUMAN "PLATELET-FREE" PLASMA: EVIDENCE FOR THE EXISTENCE OF A "PLASMA THROMBOPLASTIN"

By C. LOCKARD CONLEY, ROBERT C. HARTMANN, AND WILLIAM I. MORSE, II

(From the Division of Clinical Microscopy, Department of Medicine, The Johns Hopkins University and Hospital, Baltimore, Maryland)

(Received for publication October 8, 1948)

The precise role of platelets in the coagulation of blood has long been a matter of debate. According to the classical theory of blood coagulation, platelets are the most important source of the thromboplastic substance necessary to convert prothrombin to thrombin (1). On the other hand Lenggenhager (2, 3) believes that platelets play no part in the initiation of coagulation. It is a well-known fact that patients with thrombocytopenia rarely have defective blood coagulation as measured by the usual laboratory tests. Aggeler and his associates (4) in a recent study of 404 patients found no statistically significant correlation between platelet counts and the clotting times of whole blood. While in most cases of thrombocytopenia the clotting time of whole blood is normal, there may be a diminished consumption of prothrombin during clotting (5). Quick (6) has shown that there is a decreased consumption of prothrombin during the clotting of plasma in which the platelet concentration has been reduced by centrifugation.

Studies on the function of platelets in coagulation have been hampered by the difficulty of rendering plasma to which no anticoagulant has been added platelet-free before spontaneous coagulation occurs. However, the addition of anticoagulants has not simplified the problem. Quick (7) has called attention to the acceleration of clotting produced by decalcification and subsequent recalcification, presumably as a result of physico-chemical alterations in which platelet rupture may play a major part.

Numerous studies have been undertaken using decalcified blood. Eagle (8) has shown that the clotting time of oxalated plasma upon recalcification varies inversely with the concentration of platelets. Cramer and Pringle (9) and Eagle (8) found that oxalated plasmas after Berkefeld filtration were incoagulable upon recalcification. How-

ever, in view of our present knowledge it seems quite likely that the prothrombin was removed in the process of filtration.

Brinkhous (10) studied the recalcified plasma clotting time of citrated human plasma collected in silicone-treated apparatus. After 22½ hours of centrifugation at 14,000 RPM (about 14,000 g), this plasma was incoagulable upon recalcification. Centrifugation for 165 minutes failed to produce incoagulable plasma. This difference in clotting behavior was presumed to be due to the complete removal of platelets after the prolonged centrifugation. The author concluded that the clotting of normal plasma depends on the presence of formed elements. No platelet counts were recorded. In our experience platelets can be completely removed at 14,000 g in much less time than 165 minutes. In Brinkhous' experiment the failure of the plasma to clot might well be explained by changes not related to platelets.

A number of attempts have been made to prepare platelet-free plasma without anticoagulants. Bordet and Gengou (11, 12) collected blood in paraffin-coated vessels and removed the formed elements by centrifugation. The supernatant plasma was found to clot promptly when placed in glass tubes, but the clotting time in paraffined tubes was greatly prolonged. These authors believed that initiation of coagulation was brought about by a physico-chemical change induced in platelet-free plasma by contact with glass surfaces. Whether or not their plasmas were actually platelet-free cannot be determined.

Fuchs (13, 14) on the other hand reported the preparation of a "Stable Plasma" without the use of anticoagulants by means of special venipuncture technique, paraffin-lined apparatus, low temperatures and rapidly attained high-speed centrifugation. Although the characteristics of this "Stable Plasma" were not clearly described, Fuchs stated

that it was spontaneously incoagulable in glass and paraffined tubes. Feissly (15) and Smith, Warner and Brinkhous (16) have been unable to confirm Fuchs' observations using similar techniques.

Jaques and his co-workers (17) have introduced into blood coagulation studies a method for coating laboratory apparatus with a non-wettable surface of silicone.¹ With this apparatus it is possible to obtain a fluid plasma free of platelets without the use of anticoagulants. Jaques and his associates presented experimental data to show that as the number of platelets is reduced by centrifugation the spontaneous clotting time of this native (undecalcified) plasma becomes longer. However, their lowest reported platelet counts were in the neighborhood of 2500 per cmm., a level not approaching platelet-free. These authors believe that in silicone-coated containers the initiation of coagulation is independent of platelet action.

Quick (6) using silicone-treated apparatus found a decreased consumption of prothrombin during the process of clotting when native plasmas were subjected to "high-speed" centrifugation (3500 RPM for seven minutes) as compared to "low-speed" centrifugation. This finding was attributed to the removal of all but a few of the platelets. However, no platelet counts were recorded. Quick did not obtain spontaneously incoagulable plasmas, but he believed it highly probable that with removal of all the platelets before any disintegration occurs, a spontaneously incoagulable plasma could be obtained.

Patton, Ware and Seegers (18) studied the clotting behavior of normal dog plasma by means of silicone-treated apparatus and high-speed centrifugation. They were unable regularly to obtain spontaneously incoagulable plasma, and found that platelet-free plasma clotted as promptly in silicone-treated as in glass tubes. For this reason they concluded that there was no evidence for the view that plasma contains a soluble factor which can initiate clotting independent of platelet action. In view of the high-speed centrifugation employed (22,000–23,000 RPM) it seems possible that the plasma thromboplastic protein described by Chargaff and West (19) could have been removed in these experiments.

The purpose of our studies was to determine the clotting behavior of human platelet-free plasma

prepared by the use of silicone-treated apparatus and high-speed centrifugation.

METHODS

Preparation of "platelet-free" plasma: Needles, syringes, test-tubes and pipets were treated with silicone after the method described by Jaques (17). When drawing blood, in order to avoid contamination with tissue juice, we employed a multiple syringe technique, discarding the contents of the first syringe. Thirty to 40 ml. of blood from the second syringe were carefully placed in iced silicone-treated tubes and centrifuged at 7000 RPM (about 6000 g) at 4° C for five minutes to remove the cells and most of the platelets. The upper portion of the plasma was removed with a silicone-treated pipet and re-centrifuged at 12,000 to 14,000 RPM (17,500–22,000 g) for 10 minutes. Occasionally another centrifugation at this speed was performed. Thereafter the upper portion of this plasma was removed and stored in silicone-treated tubes in an ice bath. Normal plasma obtained in this manner remains fluid for at least several days at 4° C.

Clotting times: All clotting times were performed by a modified Lee-White three tube method at 37° C using scrupulously clean glass or silicone-treated tubes. With this technique normal individuals occasionally have a whole blood clotting time in glass tubes as long as 30 minutes, and the clotting time in silicone tubes may be much longer. For the sake of brevity only the clotting time in the third and most significant tube is recorded, although it is ordinarily wise to consider the results in all three tubes. Clotting tubes were observed for a minimum period of 24 hours.

Prothrombin times: Prothrombin times were determined by the one-stage method of Quick using a highly standardized rabbit-brain thromboplastin prepared according to the technique of Brambel (20). Since the native "platelet-free" plasma had not been decalcified, in the prothrombin estimations on this plasma 0.1 ml. of physiological saline was used in place of 0.1 ml. of M/40 calcium chloride.

Anticoagulant assays: Tests for the presence of circulating anticoagulants were performed by adding freshly drawn normal blood to the subject's "platelet-free" plasma, and noting the effect on the clotting time of the former. Details on the use of this method and its sensitivity to heparin have been reported (21).

Platelet counts: Platelet counts on whole blood were performed by a routine method employing Rees-Ecker diluent. Normal values in our laboratory are in excess of 200,000 per cmm. Platelet counts on "platelet-free" plasma were performed by introducing the undiluted plasma into a Spencer "Bright-Line" counting chamber. The use of silicone-treated cover-slips delayed clotting 30 minutes or more, enabling one to complete accurate counts. By using the fine adjustment of the microscope the entire area between the cover-slip and chamber was visualized so that platelets which had not settled to the counting chamber surface could be counted. All refractile bodies resembling platelets in any manner whatsoever

¹ General Electric Dri-Film 9987.

were counted, so that reported values are maximal and correct values are probably somewhat lower.

Preparation of plasmas with varying platelet concentrations: In order to study further the role of platelets in clotting, different specimens of the same native plasma were rendered "platelet-free" by high-speed centrifugation and platelet-rich by very low speed centrifugation. Platelet counts were performed, and the two plasmas then mixed in varying proportions.

RESULTS

Eighty-six human subjects were studied. Of these, 41 were normal individuals and the remainder were patients with various diseases.

NORMALS

Studies of the clotting behavior of normal "platelet-free" plasma correlated with the whole

Note: All determinations on each subject were made on a specimen obtained from the same venipuncture. All procedures were carried out at 37° C.

* In these experiments the improved technique of re-coating the silicone-treated tubes before each use was employed.

blood clotting time in glass tubes and the prothrombin time of oxalated plasma are shown in Table I.

We abandoned the routine use of silicone-treated tubes for determination of the whole blood clotting time, since the results were too variable, poor clots were formed, and it was difficult to recognize end-points. The clotting time of whole blood in silicone-treated tubes seems to be more a measure of imperfection in technique than of the inherent properties of the blood. Theoretically blood should not clot in silicone-treated tubes if technique were perfect.

It was not always possible to obtain a plasma entirely free of refractile bodies even when repeated high-speed centrifugations were used. It seemed unlikely that all of these refractile bodies were platelets, although they must be presumed to be and were recorded as such. In some instances platelets appeared to be completely absent. To emphasize the extremely small number of platelets remaining after centrifugation we have called these plasmas "platelet-free" in contrast to the "deplateletized" plasmas of Tocantins (22) which contained as many as 20,000 platelets per cmm. Furthermore, we found no difference in behavior of plasmas containing 0 to 100 platelets per cmm.

Normal "platelet-free" plasmas invariably clotted in glass tubes at 37° C in a relatively short time. There was considerable variation in the time required for this clotting. In most instances, however, the clotting time of normal "platelet-free" plasma in glass tubes was longer than that of the whole blood from which it was derived. Even with careful technique it was rarely possible to demonstrate a perfect correlation between platelet counts and clotting times (Table II). With

platelet counts under 1000 per cmm. there appeared to be no correlation between platelets and clotting time. Completely platelet-free plasmas did not have clotting times longer than plasmas containing a few platelets.

Clotting of normal platelet-free plasma in glass tubes could be prevented by the addition of sodium oxalate. This indicates that thrombin did not exist in the platelet-free plasma prior to its introduction into glass tubes. As a matter of fact, no thrombin was demonstrable until immediately prior to the onset of visible clotting.

In our early experiments we did not recoat the silicone-treated clotting tubes before each use. Under these conditions the clotting times of "platelet-free" plasmas in silicone-treated tubes were not always significantly longer than the clotting times in glass tubes. When freshly prepared silicone-treated tubes were used, a significant difference was constantly observed. In fact, in four cases (cases Nos. 33, 36, 37, 39) *the plasmas formed no clots in silicone-treated tubes at 37° C.* In two of these there was a very slight precipitation of some amorphous material but no true clot formation. In the other two cases, although the plasmas became slightly cloudy after several hours, there was not the slightest evidence of precipitation or fibrin formation. It seems possible that with constantly perfect technique one could regularly obtain platelet-free plasmas spontaneously incoagulable in silicone-treated tubes at 37° C.

When thromboplastin was added to these "platelet-free" plasmas, prompt clotting occurred in glass or silicone-treated tubes. The prothrombin times of these plasmas were almost the same as the prothrombin times of oxalated plasmas obtained from the same venipuncture. Native "platelet-free" plasmas maintained their prothrombin activity as measured by the one-stage method when they were stored in a frozen state, whereas the prothrombin times of frozen oxalated plasmas became a few seconds longer. Freezing and thawing of "platelet-free" plasma in silicone-treated tubes resulted in shortened clotting times.

The mechanism of clotting of "platelet-free" plasma was observed in Spencer "Bright-Line" counting chambers. Clotting occurred first on the cover-slip and not until later on the silvered counting chamber surface. Clotting definitely did not

TABLE II

The relationship of the spontaneous clotting times of native (undecalcified) plasma to the number of platelets present

Platelets (per cmm.)	6	28,000	56,000	140,000	280,000	420,000	560,000
Clotting time in glass tubes at 37° C. (in minutes)	48	33	24	19	15	9	11

Note: Normal native "platelet-free" and "platelet-rich" plasmas were obtained from pooled sources by high- and low-speed centrifugations respectively. Platelet counts were performed, and the plasmas mixed in varying proportions.

begin around platelets when they were present. As clotting occurred small refractile structures appeared at the crossings of the fibers. Although no platelets may have been present before clotting occurred, thousands of these refractile structures could be seen at the fiber crossings once clotting began. If a few platelets were present, these were seen to settle to the chamber surface and disappear only after clotting was well under way.

By altering the platelet concentrations of plasmas we were able to demonstrate that the degree and speed of clot retraction varied directly with the number of platelets present. This correlation was poor and irregular in glass tubes but excellent in silicone-treated tubes. Clot retraction occurred promptly with platelet-counts as low as 20,000 per cmm. in silicone-treated but not in glass tubes. The clots of platelet-free plasmas did not retract either in glass or in silicone-treated tubes.

The dynamics of the coagulation of platelet-free plasma in glass tubes was studied by determining the time of thrombin appearance, fibrinogen utilization, and prothrombin consumption. Results of a representative experiment are shown in Table III. In general there was minimal prothrombin

consumption even over a period of several hours.

In order to investigate a possible quantitative relationship between platelet concentration and the amount of prothrombin converted in the process of clotting, prothrombin times of the residual serum after clotting were determined using plasmas containing varying numbers of platelets. The results in Table IV show a striking correlation even at the higher platelet levels when glass tubes were used. In silicone-treated tubes prothrombin consumption was minimal regardless of the number of platelets present.

High-speed centrifugation did not prolong the prothrombin time of native plasma when rabbit brain extract was used as a source of thromboplastin. However, prothrombin times with Russell's viper venom² were greatly prolonged by high-speed centrifugation. Similar observations on oxalated plasmas were reported by Macfarlane (23).

Plasmas from fasting individuals gave the best results in our experiments. In grossly fatty plas-

TABLE IV

The relationship of prothrombin consumption in the clotting of native plasma in glass tubes to the number of platelets present, as measured by the determination of prothrombin times on serum expressed from the clots four hours after clotting

Platelets (per cmm.)	6	175,000	262,500	350,000
Clotting times in glass tubes at 37° C. (min.)	14	10	7	10
Prothrombin time of expressed serum 4 hours after clotting (sec.)	20	63	80	141

The plasmas with various platelet concentrations were prepared by mixing platelet-free and platelet-rich plasmas from the same source.

The prothrombin times were determined by adding 0.1 cc. of the expressed serum to a mixture of 0.1cc. thromboplastin and 0.1 cc. prothrombin-free plasma at 37° C. and measuring the time required for clotting.

mas coagulation often occurred in the lipid layer at the top of the tube after centrifugation.

Hemophilia

Seven patients with hemophilia were studied. Results are shown in Table V. In every instance the "platelet-free" plasma was spontaneously incoagulable in glass and silicone-treated tubes at 37° C regardless of the length of the whole blood

clotting time. No trace of fibrin was noted in any of the tubes even after a period of days or weeks. Yet the addition of rabbit brain thromboplastin produced prompt clotting, with prothrombin times comparable to those of oxalated plasmas. When hemophilic blood was centrifuged in lusteroid tubes untreated with silicone, the resultant platelet-free plasma clotted. The silicone surface therefore appeared to be necessary for the preparation of spontaneously incoagulable hemophilic platelet-free plasma. When whole blood clotting times on hemophilic blood were performed in silicone-treated tubes, the clotting times were tremendously prolonged and in some instances no clotting occurred regardless of the clotting time in glass tubes.

One untreated hemophilic patient (Case No. 42) had a normal whole blood clotting time ranging from 12 to 25 minutes during an active bleeding episode. A platelet-rich plasma obtained by low-speed centrifugation had approximately the same clotting time. However, the "platelet-free" plasma was spontaneously incoagulable in glass and silicone tubes. Thus it appears that platelets are necessary for the clotting of hemophilic plasma, although our present results are compatible with the

* This patient had a positive test for the presence of circulating anticoagulant.

view that they are not necessary for the initiation of coagulation of normal plasma.

The hemophilic "platelet-free" plasmas were tested for antithromboplastic properties by determining prothrombin times with progressively diluted thromboplastin solutions. For this we used silicone-treated tubes and native "platelet-free" plasma. The results shown in Table VI reveal no definite evidence for the presence of antithromboplastic activity in hemophilic plasma. In one experiment the native plasmas were first oxalated, then incubated several minutes with thromboplastin solutions and finally recalcified. Results were the same in this experiment. Variations in the clotting times obtained with highly diluted thromboplastin solutions must be interpreted with great caution since under such circumstances it is technically difficult to reduplicate results.

Heparinized blood

"Platelet-free" plasmas were obtained from normal individuals after the intravenous injection of small quantities of heparin. In other experiments heparin in small amounts was added *in vitro* to normal "platelet-free" plasma. Results shown in Table VII demonstrate that even after minute doses of heparin, so small that the whole blood clotting times were not affected, the "platelet-free" plasmas would not clot in glass or silicone-

treated tubes at 37° C. The *in vitro* addition of minute amounts of heparin likewise resulted in the production of incoagulable plasma. The authors (24) have previously shown that there is an inverse relationship between the action of heparin and platelet concentration. With low concentrations of heparin, prothrombin determinations on the "platelet-free" plasmas gave normal results.

Dicumarolized patients

Five patients with hypoprothrombinemia due to dicumarol were studied. Results are shown in Table VIII. While the findings are somewhat variable, the "platelet-free" plasmas of these patients were often spontaneously incoagulable in glass or silicone-treated tubes at 37° C. On two occasions these plasmas gave suggestively positive tests for the presence of circulating anticoagulant. The addition of solutions of thrombin to oxalated plasmas of dicumarolized patients resulted in longer clotting times than the addition of the same thrombin solution to normal plasmas. Further studies are in progress regarding this finding.

Thrombocytopenia

Studies were performed on 12 patients with hemorrhagic diathesis associated with thrombo-

cytopenia (Table IX). Three of these patients had marked prolongation of their whole blood clotting times and in each of these instances the "platelet-free" plasmas were spontaneously incoagulable in glass and silicone-treated tubes. Eight patients with essentially normal whole blood clotting times had "platelet-free" plasmas which clotted in glass tubes in a perfectly normal fashion. In all of our cases of thrombocytopenia a sensitive test for circulating anticoagulant was negative. In order to eliminate the possibility that failure of

the three "platelet-free" plasmas to clot in glass tubes could be attributed to the presence of anticoagulant in quantities too small to be detected by our routine anticoagulant assay, a further study was carried out in one case. Spontaneously incoagulable "platelet-free" plasma from patient No. 73 was added to normal "platelet-free" plasma in glass tubes. Five tenths ml. of the patient's plasma failed to prevent coagulation of 1.0 ml. of normal "platelet-free" plasma, conclusively demonstrating the absence of anticoagulant.

TABLE VIII

The clotting behavior of "platelet-free" plasma from patients with hypoprothrombinemia due to dicumarol

Patient	Whole blood clotting time in glass tubes	Pro-thrombin time of oxalated plasma	"Platelet-free plasma"

All of the determinations were made at 37° C.

Miscellaneous patients

Table IX shows the results of studies on a group of patients with hemorrhagic diathesis associated with a variety of conditions. Detailed studies on the two patients with "undiagnosed disease due to circulating anticoagulant" have already been reported (25).

The patients with liver disease were of great interest. The two (Cases Nos. 81, 82) whose "platelet-free" plasma did not clot had positive tests for circulating anticoagulant as well as a severe hypoprothrombinemia. Furthermore, the clotting times of their plasmas after the addition of a thrombin solution were tremendously prolonged as compared to the clotting times of normal plasmas, although the fibrinogen concentrations were adequate. We therefore believe that these patients had circulating antithrombic anticoagulants. The rate of fibrinolysis of the sterile recalcified plasma clot was determined in these two cases by Dr. Oscar Ratnoff. The clot lysis time of patient No. 81 was normal, but that of patient No. 82 was shortened. There was no evidence that the coagulation defect was caused by increased proteolytic activity of the serum. Many patients with more markedly increased proteolytic activity of the serum showed no abnormality of blood coagulation.

In view of the reported occurrence of circulating heparin-like anticoagulant after treatment of Hodg-

kin's disease with nitrogen mustards³ (26), three such patients were studied. None of these patients developed hemorrhagic diathesis and tests for circulating anticoagulant were negative. Their "platelet-free" plasmas were similar to those of normal individuals (Table X).

DISCUSSION

The use of silicone-treated apparatus has made possible the satisfactory preparation of a "platelet-free" plasma without the use of anticoagulants. Employing this technique we have been able to study the clotting behavior of human plasma. The most significant finding has been that *normal "platelet-free" plasma clots in a relatively short time in glass tubes at 37° C, but its clotting time in silicone-treated tubes is markedly prolonged and sometimes there is no clotting at all.* This observation suggests that contact with glass activates some plasma constituent which can initiate clotting. This factor is apparently activated slowly or not at all by contact with silicone-treated surfaces. We believe that with constantly perfect technique, platelet-free plasma would regularly be spontaneously incoagulable in silicone-treated tubes.

We have no information concerning the origin and nature of this plasma factor. It is quite possible that during the manipulations involved in our experiments a few platelets may have been broken up. However, if active thromboplastic substance were liberated in this manner, it seems reasonable to assume that the clotting time of platelet-free plasma would be the same in silicone-treated tubes as in glass tubes. There is no evidence that a silicone surface itself interferes with the clotting process, for on addition of highly diluted thromboplastin to platelet-free plasma, clotting occurs as promptly in silicone-treated tubes as in glass tubes. We are therefore unable to escape the conclusion that an inactive thromboplastin precursor in plasma is activated on contact with glass surfaces.

The existence of a plasma thromboplastin independent of platelets has been postulated by some workers (2, 3). Howell (27) believed that a continuous destruction of platelets *in vivo* led to the

formation of a plasma thromboplastin, as was previously suggested by Morawitz (1). Lozner and Taylor (28) maintain that the effect of foreign surfaces such as glass is not due to lysis of platelets but rather to activation of a plasma thromboplastin. Owren (29) has presented data to refute Lenggenhager's (2, 3) conclusions concerning the existence of a plasma thromboplastic factor and considers that no substantial evidence has been

presented. On the other hand, Chargaff and West (19) by ultracentrifugation of platelet-free plasma have obtained a sediment with potent thromboplastic properties. Quick (6) and Brinkhous (10) using techniques similar to those which we have employed have concluded that normal plasma contains a soluble factor whose interaction with platelets is necessary for normal blood coagulation. However, these authors do not believe

that the plasma factor can initiate clotting in the absence of platelets.

Recent discovery of several patients with a curious type of circulating anticoagulant (25, 30) lends strong support to the theory of the existence of a plasma thromboplastin precursor. Although the plasmas of these patients contained a potent clotting inhibitor, they reacted in a perfectly normal way to highly diluted thromboplastin. It is apparent, therefore, that the action of the circulating anticoagulant in these cases preceded and in some way prevented the liberation of active thromboplastin. These observations can be explained only by assuming that the clotting inhibitor delays conversion of a thromboplastin precursor to an active thromboplastin.

While our studies show that platelets do not appear to be necessary for the initiation of clotting, it is clear that they increase the rate of clotting and the amount of prothrombin consumed in the process. There is a close correlation between the number of platelets present and the amount of prothrombin converted during clotting in glass tubes. Other observers (5, 6) have previously noted that in thrombocytopenic blood little prothrombin is consumed during clotting. The prothrombin consumed in the coagulation of platelet-free plasma is minimal.

Hemophilic platelet-free plasmas were invari-

ably spontaneously incoagulable in glass tubes at 37° C although they clotted promptly on the addition of thromboplastin. This suggests that the defect in hemophilia is a deficiency of the plasma thromboplastic factor. It is apparent that hemophilia is not caused by any defect in platelets, but rather that the presence of platelets is what makes hemophilic blood clot at all. Even when an untreated hemophilic patient (*e.g.* Case No. 42) has a normal whole blood clotting time, the hemorrhagic diathesis may persist. This indicates that the plasma thromboplastin is necessary for normal hemostasis regardless of the clotting time of the blood *in vitro*. Presumably the "antihemophilic globulin" (31) is identical with the plasma thromboplastin precursor.

Whether or not the plasma thromboplastic factor is totally absent from hemophilic blood has not been established. Lenggenhager (32) believed that it was present in hemophilia but abnormally resistant to activation. Craddock and Lawrence (33) have presented data to indicate that "antihemophilic globulin" may be antigenic in hemophilic subjects. If their observations are correct, it must be presumed that hemophiliacs are entirely devoid of this plasma component.

Quick (34) observed that high-speed centrifugation of oxalated hemophilic plasma caused marked prolongation of the recalcified clotting time.

Quick originally believed that platelets were abnormally resistant in hemophilia, and that they could therefore be removed by centrifugation before thromboplastin was liberated. Rather, it seems to us that the results of Quick's experiment again demonstrate that platelets are critically necessary for the clotting of hemophilic plasma.

Hemophilic blood, presumably lacking in plasma thromboplastic factor, will clot if platelets are present, although clotting is delayed and incomplete. Likewise, normal plasma will clot in the absence of platelets, but in this instance also coagulation is incomplete. It appears that both the platelet and plasma factors are necessary for normal coagulation, although either one alone will suffice to initiate coagulation. The nature of the interaction between platelets and the plasma factor remains to be elucidated.

No evidence was obtained to support the theory that the primary defect in hemophilia is an increased antithromboplastic activity of the plasma. We were unable to demonstrate any antithromboplastic activity of the plasma of our hemophilic patients even when a potent clotting inhibitor was present (Case No. 43).

Normal platelet-free plasma containing an exceedingly low concentration of heparin is spontaneously incoagulable at 37° C even though the prothrombin time upon the addition of thromboplastin is normal. The inverse relationship between heparin activity and platelet concentration has already been reported (24). Studies on the precise mode of action of heparin in platelet-free plasma will be published later.

Experiments on the plasmas of patients with hypoprothrombinemia due to dicumarol gave variable results. In most cases the "platelet-free" plasmas were spontaneously incoagulable in glass tubes. We are unable to account for this on the basis of hypoprothrombinemia alone. Two patients temporarily showed suggestive evidence of circulating anticoagulant. The oxalated plasmas of dicumarolized patients clotted more slowly on the addition of thrombin solution than did normal plasmas. Further studies will be necessary to explain these results.

The "platelet-free" plasmas of most of the patients with thrombocytopenia behaved in a normal manner. However, in each of three cases with prolonged whole blood clotting times the "platelet-

free" plasma was spontaneously incoagulable. We are unable to explain the prolonged whole blood clotting time and associated failure of platelet-free plasma to clot in three cases. It is apparent that these deviations from normal were caused by a deficiency of a thromboplastic factor rather than by the presence of a clotting inhibitor. The numerical reduction of platelets alone is not sufficient to account for the coagulation defect, and we can only surmise that there must have been a deficiency also of a plasma thromboplastin. These plasmas could not be distinguished from those of the hemophiliacs. Other cases of thrombocytopenia with unaccountably prolonged whole blood clotting times have been reported (35).

Two of the three patients with fatal liver disease (Cases Nos. 81 and 82) had positive anti-coagulant assays and their "platelet-free" plasmas did not clot. We have presented evidence that these patients had plasma antithrombic anticoagulants in addition to severe hypoprothrombinemia. By contrast, the "platelet-free" plasma of the third patient (Case No. 83) clotted in glass tubes in spite of a severe hypoprothrombinemia, and this patient had no evidence of circulating anticoagulant.

Three patients with Hodgkin's disease treated with nitrogen mustard showed no evidence of a disturbance of blood coagulation, and their "platelet-free" plasmas were similar to those of normal individuals. The heparin-like anticoagulant reported by Smith *et al.* (26) to occur following nitrogen mustard therapy was not demonstrable in our cases.

SUMMARY

1. By means of silicone-treated apparatus and high-speed centrifugation at low temperature it has been possible to prepare fluid platelet-free plasma without the use of anticoagulants.

2. Studies on the "platelet-free" plasmas of 86 human subjects with and without hemorrhagic diathesis are presented.

3. Evidence is submitted for the existence of a soluble plasma thromboplastin precursor which on contact with glass surfaces is converted to an active state. Both this plasma factor and platelets are necessary for normal coagulation, but clotting can be initiated by either alone.

4. The coagulation defect in hemophilia appears to be a deficiency of this plasma thromboplastin precursor.

THE HEMODYNAMIC EFFECTS OF HYPOTENSIVE DRUGS IN MAN.¹ I. VERATRUM VIRIDE

By EDWARD D. FREIS, JOSEPH R. STANTON, JAMES W. CULBERTSON,
JULIUS LITTER,² MEYER H. HALPERIN, CHARLES H.
BURNETT, AND ROBERT W. WILKINS

(From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of
Medicine, Boston University School of Medicine, Boston)

(Received for publication October 5, 1948)

INTRODUCTION

Renewed interest in veratrum viride began with the investigations of Craig and Jacobs (1) who isolated the veratrum alkaloids and found them to be sterol compounds related chemically to the digitalis glycosides, the steroid hormones and vitamin D. Using the pure alkaloids, Krayner and his co-workers (2) demonstrated that sub-toxic doses in experimental animals produced a vasodepressor response of reflex nature. They found that the most important receptor area for the reflex was located in the left ventricle of the heart, and that the primary afferent pathway was the vagus nerve. They did not determine the efferent pathways of this vasodepressor response.

Meanwhile, clinical interest in veratrum viride steadily increased because of its therapeutic use in the eclamptic toxemias of pregnancy (3, 4) and, more recently, in cases of severe essential hypertension (5). Nevertheless, very little was known of its hemodynamic or other pharmacologic effects in human beings. The present study was undertaken to elucidate the actions of the drug in both hypertensive and normotensive individuals.

MATERIALS AND METHODS

The subjects were patients, mostly hypertensive, admitted to the Massachusetts Memorial Hospitals. Both oral (Vertavis³) and parenteral (Veratrone⁴) preparations of veratrum viride were administered. Arterial pressure was measured either with a Hamilton manometer (6) (during the determinations of vasopressor responses, cardiac output, and/or hepatic-portal blood

flow); or with an arm cuff and a mercury manometer. Cardiac output was determined directly by the Fick principle using the intravenous catheter method of Courmand (7) and determinations of blood oxygen by the method of Van Slyke and Neill (8). In order to insure complete mixing, the venous blood samples were withdrawn always from the pulmonary artery, while oxygenated blood was taken either from the brachial or the femoral artery. Ballistocardiograms (9, 10) were recorded simultaneously in these and other hypertensive subjects but due to the abnormal ballistocardiographic complexes occurring in patients with hypertension, accurate measurements of cardiac output by this method were not possible. Blood flow in the forearm and calf was determined plethysmographically by the method of Wilkins and Eichna (11), modified by the use of a thin rubber sleeve instead of the rubber diaphragms cemented to the skin (12). Hepatic-portal (splanchnic exclusive of renal and adrenal) blood flow was estimated by the bromsulfalein method of Bradley *et al.* (13), with three modifications: first, peripheral blood samples consistently were arterial; second, determinations of BSP were made on oxalated plasma rather than serum; and third, estimations of blood flow rate were calculated for the times at which arterial blood samples were drawn. Renal plasma flow (PAH) and glomerular filtration rate (mannitol, inulin) were determined by the methods of Smith and his co-workers (14).

Vasopressor overshoots after blood-pressure-lowering procedures were measured by the method of Wilkins and Culbertson (15), reflex vasoconstrictions in the digits by the method of Bolton, Carmichael and Stürup (16) and skin temperature responses according to the method of Uprus, Gaylor and Carmichael (17). Vascular distensibility in the extremities was determined using the method of Litter and Wilkins (18).

RESULTS

I. Cardiac function

Cardiac output, mean arterial pressure and total peripheral resistance

Control and experimental determinations were carried out during a single test on five patients given Veratrone by intramuscular injection. In two other patients a control study was done, after

* Oral veratrum viride given twice per day for one week after control test in four equal hourly doses (time counted from beginning of last dose).

† Parenteral—given intramuscularly immediately following control period.

‡ Determined by planimetric measurement of the arterial pulse waves.

EFFECT OF VERATRUM ON PULSUS ALTERNANS AND BCG

FIG. 1. OPTICAL RECORDS OF THE BALLISTOCARDIOGRAM AND THE BRACHIAL ARTERIAL PRESSURE (HAMILTON) BEFORE AND AFTER THE ORAL ADMINISTRATION OF 30 CRAW UNITS OF VERATRUM VIRIDE IN PATIENT M. A., MALE, AGED 43

Pulsus alternans was present in the control record. Following veratrum there was a marked reduction in arterial pressure, a disappearance of pulsus alternans, and a return of the ballistocardiogram to a more normal pattern.

which Vertavis was administered orally for one week before the determinations were repeated. The results in both types of experiments were essentially the same (Table I). In all but two of the

seven cases there was a fall in mean arterial pressure of from 8 to 28 per cent, and in three patients, of more than 20 per cent. However, during the period of reduced blood pressure depression of cardiac output was not observed. Rather, in three cases, there was a slight increase in cardiac output of 6 to 8 per cent, and in two patients, with congestive heart failure, an increase of 20 and 24 per cent. As a result of the significant fall in mean arterial pressure and slight rise in cardiac output there was a considerable decrease in the calculated total peripheral resistance (between 30 and 35 per cent in four of the cases and of 11 per cent in one case). In two cases (M. H. and J. C., Table I) there were insignificant changes in cardiac output or peripheral resistance during the time the cardiac output determinations were being carried out, the major portion of the test period in patient M. H. having been devoted to estimations of hepatic-portal blood flow (Table III, Figure 5).

Other aspects of cardiac function

It was not unusual to observe a decrease in cardiac enlargement as measured by roentgenography (5) in patients who exhibited a prolonged reduction in blood pressure after months of continuous oral administration of veratrum viride. Less frequently, changes toward normal in the electrocardiogram were observed. Pulsus alternans usually decreased or disappeared during the reduc-

FIG. 2. OPTICAL RECORDS OF RESPIRATION AND BRACHIAL ARTERIAL PRESSURE (HAMILTON) IN PATIENT C. B., FEMALE, AGED 49

Ninety minutes following the oral ingestion of 20 Crawl units of veratrum viride (second tracing) there was a fall in arterial pressure accompanied by bradycardia. Atropine (1 mgm. intravenously) was given immediately, and three minutes later (third tracing) there was a tachycardia and a rise in diastolic but not in systolic pressure. The diastolic rise was more apparent than real since it was associated with shortening of the run-off period.

* Parenteral—given intramuscularly immediately following control period.

tion of blood pressure following veratrum viride, and the ballistocardiogram also occasionally reverted toward a more normal form (Figure 1).

Pulmonary congestion lessened and dyspnea improved during the hypotensive action of veratrum. For example, patient J. Mc. (Table I) at the time of the control cardiac output determination exhibited clinical evidences of cardiac failure, including dyspnea and pulmonary congestion. After Veratrone, the systemic arterial pressure de-

clined from 290/185 to 230/135 while the pulmonary arterial pressure fell from 90/60 to 58/28 mm. Hg and the cardiac stroke volume increased from 32 to 48 ml. At this time the patient noted subjective relief of dyspnea. The injection of Veratrone was followed by a decrease in pulmonary arterial pressure in the three cases who exhibited abnormal elevations (Table I).

Bradycardia was frequently observed after veratrum viride and was shown to be vagal in origin

by the fact that it could be abolished by the intravenous injection of 1 mgm. of atropine. Although atropine abolished the bradycardia it did not greatly affect the reduction in blood pressure (Figure 2). In occasional patients bradycardia was not manifested following Veratrum even though the arterial blood pressure was significantly reduced (case W. G., Table I). Thus, bradycardia appeared to be a common, perhaps an augmenting, but not a necessary accompaniment of the hypotensive response.

II. Blood flow through various regions

Blood flow through the forearm and calf

All six hypertensive patients who were studied plethysmographically following the intramuscular injection of Veratrone (Table II), had a decrease in mean arterial pressure of from 8 to 38 per cent. The blood flow to the forearm in two of the six subjects decreased as the arterial pressure fell, but returned to control levels as the arterial pressure became stabilized at a lower level. In three subjects, as the pressure fell the blood flow in the forearm increased and remained elevated, while in one the flow was unchanged. The blood flow in the calf followed a similar pattern, falling in two of five cases but returning to control levels before the blood pressure, increasing in two, and remaining unchanged in one. Since in all of these patients

blood flow remained at or returned to or above control values during the hypotensive response to Veratrone a decrease in peripheral resistance in the limbs was assumed to have occurred.

Blood flow through the hepatic-portal circuit

The blood flow through the liver (EHBF) was estimated in three hypertensive patients in the basal state and horizontal position both before and after administration of veratrum viride (Table III). In the first patient, W. G., two separate studies were made, one for control measurements and the other after a week of treatment with Vertavis tablets by mouth. The latter study revealed an increase of 25 per cent in the average EHBF and a decrease of 27 per cent in the average "mean" ($= \frac{S + D}{2}$) arterial pressure, indicating a significant reduction in hepatic-portal vascular resistance.

In the two other cases acute experiments were performed. After a period of control observations, patient J. C. received 0.6 ml. of Veratrone solution intramuscularly. Twenty minutes later, because there had been no evidence of a hypotensive response, but on the contrary, a moderate pressor reaction, he received a dose of 0.2 ml. of Veratrone. Twelve minutes after the second injection, EHBF and arterial pressure had decreased from control values by 12 per cent and 32 per cent respectively, and at 22 minutes by 21 and 46 per cent respec-

† Clot in needle prevented accurate recording of arterial pressure.

FIG. 3. CHART OF ESTIMATED HEPATIC-PORTAL BLOOD FLOW (EHBF), ARTERIAL PRESSURE (HAMILTON), AND PULSE RATE IN PATIENT M. H., FEMALE, AGE 50

Above are the infusion and removal rates, the arterial and hepatic venous concentrations and the extraction rate of bromsulfalein. In the middle are data on hepatic and pulmonary A-V oxygen differences, cardiac output (Fick), cardiac index and hepatic oxygen consumption. Observed data are represented by solid symbols and lines, calculated values by open symbols and lines. Following the injection of 0.7 ml. of Veratrone (vertical line) there was a significant fall in arterial pressure. The estimated hepatic blood flow fell off slightly during the first 30 minutes after the drug and then increased above the highest level recorded in the control period.

tively. Thus, a reduction in hepatic-portal vascular resistance became apparent, but the hypotensive reaction then became excessive, and proceeded to a state of collapse with arterial pressure of 90/48 mm. Hg, pulse rate of 75 beats per minute, and development of nausea and vomiting. Therefore, experimental observations were discontinued and restorative therapy was instituted. While this case illustrates acute hemodynamic changes strikingly, it serves also as an example of the effects of overdosage.

The third patient, M. H., was observed similarly before and after a single injection of 0.7 ml. of Veratrone, which in this instance proved to be less than the optimal therapeutic dose and produced only a modest reduction in arterial pressure (Table III, Figure 3). Nevertheless, EHBF re-

mained above the lowest control value and finally rose above the highest control value at a time when "mean" arterial pressure had become stabilized at a level definitely (17 per cent) below the average control. Hence, this case also is consistent with the others in indicating that a significant reduction occurs in hepatic-portal vascular resistance following treatment with veratrum viride.

Blood flow through the kidneys

Changes in renal blood flow were similar to those observed in hepatic blood flow after veratrum viride. In two (W. G. and A. D.) of three cases maintained for one week on continuous oral administration of the drug (Table IV), the effective renal plasma flow increased moderately despite significant reductions in arterial pressure. In the

third (B. H.) it remained unchanged. In all of seven cases who received veratrum viride acutely by intramuscular injection (Table IV) there was an initial decrease in renal plasma flow followed in the later period by a return to control values. In five of these cases renal blood flow after veratrum rose to levels above those recorded in the control period (Figure 4, Table IV).

Estimations of cardiac output, hepatic-portal and renal blood flows were carried out in a single subject (case W. G., Tables I, III and IV) both before and after one week of treatment with orally administered veratrum viride. Following the cardiac output determinations the intravenous catheter was moved from the right pulmonary artery to an hepatic vein, urine samples being obtained meanwhile through a bladder catheter. These procedures permitted estimation of the percentage of the cardiac output circulating through the hepatic-portal and renal vascular beds before and after veratrum viride. In the control period the mean cardiac output was 6.55 L. per min., the average estimated hepatic-portal blood flow was 1.2, and the mean renal blood flow was 0.565 L. per min. After one week of continuous oral administration

of veratrum viride the mean values were for cardiac output 7.0 L. per min., for estimated hepatic-portal blood flow 1.48 L. per min., and for renal blood flow 0.612 L. per min. Thus, estimated hepatic-portal blood flow utilized 18.3 per cent of the cardiac output before the drug and 21.7 per cent after the drug; renal blood flow utilized 8.6 per cent of cardiac output prior to treatment and 8.7 per cent after treatment. These results suggest that despite a reduction in arterial pressure from approximately 225/130 to 170/92 the percentage of the cardiac output utilized by the hepatic-portal and renal vascular beds showed no significant change.

III. Renal function

In addition to the studies of renal plasma flow just described, measurements of glomerular filtration, filtration fraction and urine volume were also made (Table IV). Four of the patients exhibited advanced renal disease characterized by abnormally low clearances of inulin and para-aminohippurate.

Mannitol clearance following veratrum appeared to fall and remain low. Inulin clearance

FIG. 4. CHART OF RENAL PLASMA FLOW, GLOMERULAR FILTRATION RATE, FILTRATION FRACTION, RENAL EXTRACTION OF PAH, BRACHIAL ARTERIAL PRESSURE, URINE VOLUME AND HEART RATE BEFORE AND AFTER INTRAMUSCULAR VERATRUM IN PATIENT E. S., FEMALE, AGED 44

Oliguria appeared early, and remained marked even when the renal clearances had returned to control levels. Note relatively constant extraction of PAH.

first fell and then returned approximately to control values in five patients (Table IV) while in one patient (B. H., Table IV), who had marked impairment of renal function and low clearances in the control period, the inulin clearance fell and remained below the control values.

In contrast to the relatively moderate fluctuations in effective renal plasma flow, in glomerular filtration rate (inulin) and in filtration fraction, the urine volume was invariably and often strikingly reduced after the parenteral injection of veratrum viride (Table IV, Figure 4). The oliguria was associated with a marked increase in the U/P ratio of inulin or mannitol, clearly indicating that the diminished urine flow was due to increased tubular reabsorption of water. The marked rise in U/P ratio of para-aminohippurate was shown in one case (E. S., Table IV, Figure 4) to be due to increased water reabsorption exclusively since in this case the renal extraction of PAH as measured directly in the renal venous blood did not change

despite marked oliguria and more than tenfold increase in urine concentration of PAH.

Oliguria occurred after parenteral injections of Veratrone even when there was no perceptible reduction in blood pressure. This was demon-

strated in two normotensive subjects in whom 5 per cent glucose in water was administered intravenously at a constant rate until a steady state of urine excretion was obtained as determined by washing out the bladder at ten-minute intervals. A dose of 0.4 cc. of Veratrone caused no significant change in blood pressure, but did reduce the urine volume from 5.45 and 8.33 cc. per minute to 1.02 and 4.53 cc. per minute, respectively, in the two patients. Oliguria was not observed when the reduction in blood pressure was maintained by the continued oral administration of veratrum viride (patients W. G. and A. D., Table IV).

IV. Other hemodynamic functions

Cardiovascular reflexes—Sympathetic responses

Unlike sympatholytic agents, veratrum viride did not abolish reflex sympathetic vasoconstriction. In six hypertensive subjects the vasopressor overshoot following the Valsalva maneuver was increased in three cases, slightly decreased in two, and abolished in one after as compared with before veratrum viride (Table V, Figure 5). Postural hypotension was not observed in four subjects who were tilted to an angle of 75° for five minutes (Table VI). The hypertensive overshoot on the tilt back from the erect to the supine position was increased in two of these cases, decreased in one and not present in one case (Table VI). Postural hypotension occurred in only two of 54 patients treated clinically with veratrum viride by mouth (5). Postural hypotension with collapse never occurred with therapeutic doses of the drug.

In contrast with the depression of the cold pres-

sor response after certain sympatholytic agents (19-21) there was an augmentation after veratrum viride in two of four subjects examined and no change in the other two (Table VII). Similarly, the hypertensive response evoked in a subject by the emotional stimulus of a problem in mental arithmetic was not significantly altered during veratrum hypotension.

Reflex vasoconstriction in the digits was examined in two patients before and after the injection of veratrum viride. Finger plethysmographic recordings of the vasoconstrictor responses to a deep breath, the application of ice to the forehead and pin prick on the skin were if anything increased after veratrum viride. Further, in four patients examined in a room maintained at a constant temperature of 68° F there was no change in the skin temperature of the digits after the administration of Veratrone despite the development of marked

* Sympathectomized.

reductions in blood pressure. These various observations show that the drug did not block sympathetic reflexes.

However, evidence that the sympathetic nervous system may be involved in some way in the depressor response was suggested by the data regarding blood flow through sympathectomized extremities. The effect of Veratrone on the blood flow in sympathectomized as contrasted with normally innervated extremities was studied in five patients. Three, who were hypertensives, manifested a significant hypotensive response to the drug (Table VIII). Two of them showed a persistent decrease in blood flow in the sympathectomized extremity, whereas the flow in the normally innervated control limb was increased. In the third patient there was a slight increase in blood flow in both extremities, greater in the normally innervated limb, but the results may have been affected by the presence of considerable pain. In the two normotensive subjects similarly studied

after veratrum viride there were insignificant changes in both blood flow and arterial pressure.

Reaction to ephedrine and epinephrine

Veratrum did not abolish the pressor response and rise in heart rate following the injection of either epinephrine or ephedrine. The intramuscular injection of 0.05 gm. ephedrine promptly abolished the collapse reaction observed in three patients who were given an overdose of veratrum viride.

Vascular distensibility in the extremities

The vascular distension that occurs during venous congestion of the extremities (18) was measured in the forearm and calf in eight hypertensive and three normotensive patients before and after the intramuscular injection of Veratrone. The distension of the forearm segment in the plethysmograph during inflation of a congesting cuff to 30 mm. Hg was definitely greater after

Veratrone than before in five of 11 patients. In four the vascular distensibility was only slightly greater and in two there was no change. In the calf of one of six subjects studied there was a marked increase in vascular distensibility, in three a slight increase, and in two no change. No qualitative differences were observed between the normotensive and hypertensive cases.

Vascular distensibility measured in the sympathectomized lower extremities of two patients did not increase after Veratrone whereas in the normally innervated upper extremities it showed a marked increase. In the sympathectomized forearm of one patient there was a minimal increase in vascular distensibility after Veratrone while in the contralateral normally innervated forearm there was a marked increase.

These changes in the vascular distensibility after Veratrone occurred early and persisted for the duration of the experiments. They were usually greater and occurred earlier in the forearm than in the calf. There was little correlation between these changes and the alterations in blood pressure, blood flow, or calculated peripheral resistance.

Systemic response to venous congestion of the extremities

Previous observations in this laboratory have demonstrated that sodium nitrite and various sympatholytic agents alter markedly the systemic response of normal and hypertensive subjects to venous congestion of the extremities (22). In this test, the legs and one arm of the supine subjects were congested by cuffs placed proximally and inflated to pressures of 100 mm. Hg. After a hypotensive dose of sodium nitrite or of various sympatholytic drugs, patients frequently developed marked hypotension and collapse within two to five minutes following the application of the congesting pressure. By contrast, despite marked reductions in the resting blood pressure after veratrum, the application of such congesting pressures to the extremities for a period of five minutes was well tolerated in five subjects.

DISCUSSION

The hypotensive response to veratrum viride occurred in two phases: (1) an initial adjustment phase followed by (2) a more stable hypotensive

phase. The first phase was characterized by sharp, and often fluctuating, decreases in arterial pressure, pulse rate and peripheral blood flow. The second phase consisted of a steady state of reduced arterial pressure and pulse rate, with a return of hepatic, renal and muscle blood flows to control values. Cardiac output in the second phase was found to be essentially unchanged from the pretreatment control values. These findings along with the decreased arterial pressure were accepted as indicating a decrease in peripheral resistance.

The decrease in peripheral resistance after veratrum viride appeared to occur in all the areas under study including the retinal arterioles (5, 23). Compensatory tachycardia and palpitation of the type produced by the peripherally-acting vasodilators such as sodium nitrite or tetraethylammonium salts did not appear, nor did postural collapse occur with sub-toxic doses of the drug. Vasopressor responses to the Valsalva experiment, the erect posture, the cold pressor test and emotional stimuli remained intact. Thus, a state of circulatory equilibrium was achieved with normal cardiac output and blood flow to the vital organs in spite of the lower arterial pressure. This integrated type of hypotensive response after the crude drug was similar to that observed in experimental animals after the administration of the pure alkaloids of veratrum (2), suggesting that it too was mediated through nervous reflexes involving the higher vasomotor centers.

While the second, stable phase of the hypotensive reaction to veratrum viride was characterized by generalized vasodilatation and a return of blood flow to normal, the initial falling phase of the reaction appeared to involve different mechanisms since it not infrequently was associated with parallel decreases in peripheral blood flow. Therefore, the initial fall in arterial pressure could not always be due to a generalized decrease in peripheral resistance. A depression of cardiac output might well account for the initial fall in arterial pressure. It need not be primary in the heart but could result from a temporary failure of venous return due to dilatation of the post-arteriolar vascular beds and a consequent relative shift of circulating blood volume from the arteries to the capillaries and veins. Neither need a depression in cardiac output be sizable to cause a marked fall in arterial pressure provided it continue for some minutes. It is

known that large decreases in cardiac output such as occur with the Valsalva experiment are capable of lowering the arterial pressure of hypertensive patients to normal within a few seconds (15). An immeasurable decrease in cardiac output therefore might cause a similar effect if continued over a longer period of time such as that required for the arterial pressure to stabilize at a lower level after veratrum. Studies now in progress (24) on the changes in cardiac output during the initial phase of the hypotensive action of veratrum may reveal decreases of cardiac output to occur, but in the light of the above argument, they may not.

The oliguria which followed the parenteral injection of veratrum viride appeared to be independent of changes in either glomerular filtration rate or renal plasma flow, since suppression of urine volume continued to be most marked when these measurements had returned to or above control values. The oliguria seemed to be independent also of the level of arterial pressure inasmuch as it was observed to occur following parenteral doses of veratrum insufficient to cause a significant reduction of blood pressure, and to disappear when a continuous hypotension was maintained by prolonged oral administration of the drug. The lack of direct mechanical dependence upon either arterial pressure, glomerular filtration rate or renal plasma flow indicated that the oliguria was due to a specific antidiuretic effect. This conclusion was further substantiated by the regular occurrence of a marked rise in the U/P ratio of inulin or mannitol during the period of depressed urine volume indicating an increased tubular reabsorption of water. In addition, the extraction of PAH from the blood, as measured directly in the renal vein, did not change appreciably during the period of oliguria. These data were interpreted as indicating that the kidneys usually cleared the blood as efficiently after veratrum as they had prior to the induced hypotension but did so at first with the production of a small volume of highly concentrated urine. Therefore, the oliguria induced by the acute administration of veratrum viride did not indicate severe impairment of renal function as has been postulated previously (25), but rather a transient antidiuresis, which disappeared with continued oral treatment.

Whereas mannitol clearances fell and remained low after veratrum viride, inulin clearances fell

initially but usually returned to control values despite a continued reduction in arterial pressure. This discrepancy between the clearances of mannitol and inulin was not surprising in view of the recent evidence that under certain circumstances mannitol may be partially reabsorbed in the tubules (26). The increased tubular reabsorption of water which followed the parenteral injection of veratrum viride might well tend to accelerate the back-diffusion of mannitol, and thereby, to aggravate the discrepancy between the clearances of mannitol and inulin.

Since reflex vasopressor responses and also the vasoconstrictor reactions in the hands and feet all remained intact after veratrum viride, the drug did not appear to block sympathetic vasoconstriction. However, it is interesting that with the fall in blood pressure there was a decrease in blood flow in the sympathectomized extremities of two patients, as contrasted with the increase that occurred in the normally innervated control limbs. The decrease in the sympathectomized limbs may have been the passive result of the reduction in arterial pressure and the increase in the control limbs the result of active sympathetic vasodilatation. In this connection it was of interest also that after veratrum there was an increase in vascular distensibility in normally innervated limbs as contrasted with little or no change in sympathectomized limbs. Thus, while there was no evidence that sympathetic vasoconstrictor reflexes were blocked there was indication that vasodilator responses mediated over the sympathetic nerves might be stimulated. Finally, atropine abolished the bradycardia but did not reverse the hypotensive effect suggesting that the fall in arterial pressure was not dependent upon parasympathetic stimulation.

As a result of these studies one might draw the clinical implication that veratrum viride should be a suitable therapeutic agent in essential hypertension since it can reduce the blood pressure without harmful effects on the heart or kidneys (except when the function of the latter is severely impaired) and, since it leaves intact the vasomotor reflexes, particularly those concerned with assuming the erect posture. However, during actual clinical trial it has caused frequent toxic side reactions, the most prominent of which are nausea and vomiting (5). Work so far indicates that

these reactions may be an integral part of the reflex pattern activated by the drug (2). Therefore, the possibility of isolating or developing a compound of veratrum that will retain the desirable cardiovascular effects of the crude drug and eliminate the toxic side effects does not at present appear to be very promising.

SUMMARY AND CONCLUSIONS

Veratrum viride administered to hypertensive patients produces the following hemodynamic effects:

1. Blood flow through muscular, renal, and hepatic-portal areas usually falls initially and then returns to approximate control levels despite a continued hypotensive response. Full peripheral vasodilatation characteristically follows rather than accompanies the initial reduction in arterial pressure.

2. The output of the compensated heart remains essentially unchanged after arterial pressure is reduced. In congestive heart failure cardiac output may increase and the elevated pulmonary arterial pressure may fall.

3. Atropine abolishes the bradycardia induced by veratrum viride but only partially reverses the hypotension. Since the hypotensive effects do not depend necessarily upon a reduction in either cardiac rate or output, there is little evidence to indicate that the drug is a "cardiac depressant."

4. Effective renal plasma flow decreases only transiently and returns to control values despite a continued reduction in arterial pressure after veratrum. Glomerular filtration rate (inulin) follows a similar pattern in most cases, but occasionally remains below control values.

5. Oliguria occurs after the initial injection of veratrum viride but disappears when the hypotensive effect is continued by repeated oral administration of the drug. The oliguria is not related directly to the arterial pressure, glomerular filtration rate or renal plasma flow, but appears to be due to a specific antidiuretic effect.

6. The discrepancy between inulin and mannitol clearances is confirmed, the mannitol clearances usually remaining lower than those obtained with inulin. This discrepancy seemed to be accentuated during marked antidiuresis suggesting increased tubular reabsorption of mannitol.

7. Veratrum viride does not inhibit sympathetic vasoconstrictor responses as evidenced by the maintenance of vasopressor overshoots, skin temperature levels, vascular reflexes in the digits, the cold pressor response, and postural adaptation.

8. Vascular distensibility in the extremities usually increases, except in sympathectomized limbs, but not necessarily in association with alterations in arterial pressure, blood flow or peripheral resistance.

9. During the period of reduced arterial pressure, blood flow and vascular distensibility in sympathectomized as compared with normally innervated extremities do not increase, indicating that part of the vascular response in the limbs may be mediated over sympathetic nervous pathways possibly through sympathetic vasodilator fibers.

10. Epinephrine and ephedrine reverse the hypotensive effects of veratrum.

11. The evidence cited indicates that veratrum can produce an integrated hypotensive response which is not associated with toxic effects on either the heart or the kidneys.

SOME OBSERVATIONS ON THE BALLISTOCARDIOGRAPHIC PATTERN, WITH SPECIAL REFERENCE TO THE H AND K WAVES¹

By JOHN L. NICKERSON

(From the Department of Physiology, College of Physicians and Surgeons,
Columbia University, New York City)

(Received for publication July 26, 1948)

The origin of certain portions of the ballistocardiographic pattern has been discussed only briefly in the physiological literature. Starr and his associates (1) have given letter designations to the salient peaks and troughs and have discussed in some degree the origin of the I and J waves. Hamilton and his coworkers (2, 3) have suggested that the pattern may be due in part to the oscillations of the blood mass within the larger portions of the arterial tree. It is the purpose of the work being presented here to consider the results of some simple experiments which help elucidate in broad outline the significance of several parts of the ballistocardiograph pattern.

Two sources of information have been tapped in this study, to wit, model experiments and clinical observations. The ballistocardiograph used in this investigation was not the instrument constructed by the workers mentioned above but was the low frequency, critically damped instrument designed by Nickerson and Curtis (4). The heart model built for the study of the ventricular contribution to the ballistic pattern was a simple one-chamber device. This model ignores the asynchronism which sometimes appears between the ejection of the left and right ventricles (5, 6) and also ignores the auricular contribution to the impacts, a problem which will be dealt with in a different fashion.

The construction of the model heart is demonstrated in Figure 1. It consists of a closed elastic system of bulbs and tubing filled with water. The dimensions of the tubing approximate those of the aortic tree of an adult human. One elastic bulb is contained in a glass pressure bottle so that the force on this bulb may be raised to any suitable level. The tubing used in this system is of rubber and the bulbs are rubber balloons of various

thicknesses. This bottle has sufficient volume that the pressure changes in it during ejection are small. In operating this system, water to any desired amount (30-100 cc.) is squeezed back into the bulb in the pressure bottle at a time when the pressure bottle is open to the atmosphere. The exit tube from this bulb is then clamped shut and the pressure in the bottle raised to a measured level (40-120 mm. Hg). If now the quick-acting clamp is suddenly released by burning through a restraining thread the water in the heart bulb will be forced into the outer portions of the circulatory system corresponding to the aortic tree. This movement of fluid produces a reaction equivalent to systolic ejection. By varying the filling of the heart bulb and also the pressure in the bottle it is possible to control both the stroke volume and the force of ejection.

The normal human ballistocardiogram is illustrated in Figure 2 in which the H, I, J, K and L waves of Starr's notation are identified. It is

FIG. 1. DIAGRAM OF THE MODEL HEART

¹This investigation was supported in part by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health, U. S. Public Health Service.

FIG. 2. BALLISTOCARDIOGRAMS ON NORMAL SUBJECTS

the general view that the I-wave is produced by the footward recoil of the body and ballistic bed as a result of the headward movement of the blood at the time of its ejection from the left and right ventricles during systole. After the commencement of this footward movement, the blood, which is travelling headward, begins to fill up the aortic tree, and so slows in its course. At the same time some portion of the blood actually reverses its direction by passage around the aortic arch. These occurrences result in a large headward recoil which is sufficient to neutralize and reverse the footward movement, thus driving the ballistic system headward to produce the J-wave. Following this impact the system reaches its maximum headward deflection and since it is critically damped might be expected to return to the baseline position without overshooting. However, the blood rushing down the descending aorta does

not continue with undiminished speed but in the lower abdominal region is slowed in its footward rush, thus producing a footward thrust. This thrust is on most occasions so timed that it drives the ballistic system footward across the baseline, thus generating the K-wave. Following the K-wave there is frequently a return to the baseline. However, in many cases a subsequent headward wave, the L-wave, appears which is likely due to a reflected wave of blood travelling first up and then down the long column of the descending aorta.

That this normal pattern can be reproduced by the model heart's ejection is shown by Figure 3. Records 1 and 2 were produced by essentially the same stroke volume and ejection pressure and differ only in the greater length of the descending aorta in Record 1. The slope of the I-J line in both records is the same. Hence the stroke

FIG. 3. BALLISTOCARDIOGRAMS FROM THE MODEL HEART DEMONSTRATING VARIATION IN THE K-WAVE

In part 1 the descending aorta is long while in part 2 it is short.

volumes are equal. However, the relative depths of the K-waves are quite different. Further observation has shown that variation in the length

of the descending aorta is singularly effective in changing the K-wave and appears to be one of the chief factors determining the depth of this wave in the normal human ballistocardiogram.

Further shortening of the descending aorta or constriction of this vessel so that the blood following this course does not have a clear path below the aortic arch produces complete disappearance of the K-wave. This type of pattern is demonstrated in Figure 4A by an actual coarctation of the aorta and in Figure 4B by a coarctation at the arch of the aorta in the model experiment. Similarly in all cases of coarctation of the aorta in which it has been possible to obtain low frequency, critically damped ballistocardiograms, diminution or disappearance of the K-wave is found. It is to be noted that this absence of the K-wave is not observed when a conventional high frequency ballistocardiograph is used (see Figure 5). It is proper to state at this point that although all patterns of coarctations observed with

COARCTATION

B. Coarctation of the aorta in the model at the beginning of the descending aorta.

C and D. Pre- and post-operative records on a patient with coarctation of the aorta. The surgical procedure was the anastomosis of the subclavian artery to the descending aorta.

FIG. 5. RECORD ON A PATIENT WITH COARCTATION OF THE AORTA TAKEN WITH A LOW FREQUENCY, CRITICALLY DAMPED BALLISTOCARDIOGRAPH AND WITH A HIGH FREQUENCY, UNDAMPED BALLISTOCARDIOGRAPH

the low frequency, critically damped ballistocardiograph show this reduction of the K-wave, nevertheless a few records are seen where the K-wave is diminished without aortic coarctation being present. From analogy with the model experiments it is believed that this result appears when the effective free lengths of the major portions of the headward regions of the aortic tree and the descending aorta are essentially equal. To date only one patient with coarctation of the aorta on whom surgical treatment has been performed has had pre- and post-operative ballistic records taken. The results obtained are shown in Figures 4C and 4D. In this case the anastomosis accomplished was of the subclavian to the aorta, a procedure by which the circulation to the extremities was improved. As a result of this particular anastomosis the momentum of the blood in the descending aorta was still impeded in a region high in the thorax rather than low in the abdominal cavity as is normal. For this reason, although the movements producing the K-wave post-operatively are more accentuated than in the pre-operative pattern, the results, however, are not as completely normal as would be expected had the anastomosis been of the aorta on itself.

Another point of evidence for the development of the K-wave arises in the change of pattern on the production of a reactive hyperemia of the lower extremities. This reaction appears if the circulation to the lower limbs is occluded by pressure cuffs applied to the thighs with pressures above the systolic level for a period of 15 minutes and then released. The resulting increased oxygen demands of the tissues result in an increased blood flow to the affected parts. The changes in the ballistocardiogram are shown in Figure 6. There are two chief changes, first, an increase in

the slope of the I to J movement, thus indicating an increase in stroke volume (7, 8), and second, a decrease in the relative depth of the K-wave. This diminution of the K-wave occurs since the retardation of the blood velocity at the lower end of the descending aorta is not so great as normal, more of the blood flowing directly into the wider open vascular bed of the lower extremities. Thus the impulse producing the K-wave is less than before.

The effect of reducing the stroke volume in the model heart produces some variations in the size of the pattern. These are shown in Figure 7 where are illustrated the types of pattern found in a patient in shock. These general variations were found in all our shock cases. In this particular case the first record was made before treatment while the second and third records were made after treatment with albumin and with saline respectively. The values of the stroke volumes from the Fick data were successively 26, 37, and

REACTIVE HYPEREMIA

FIG. 6. CHANGE IN THE FORM OF THE PATTERN ON THE OCCURRENCE OF A REACTIVE HYPEREMIA OF THE LOWER LIMBS

FIG. 7. SUCCESSIVE BALLISTOCARDIOGRAMS ON A PATIENT IN SHOCK (CARDIAC INDEX BY THE FICK = 2.1), AFTER TREATMENT WITH ALBUMIN (INDEX = 2.7) AND AFTER FURTHER TREATMENT WITH SALINE (INDEX = 4.0)

The accompanying records are of the model heart with increasing stroke volume.

FIG. 8. BALLISTOCARDIOGRAMS ON THREE PATIENTS WITH AORTIC INSUFFICIENCY, ON A NORMAL SUBJECT AND ON THE MODEL HEART IN A SITUATION WHERE A LARGE STROKE IS EJECTED INTO A FLACCID AORTIC TREE

55 ml. The most significant parallelism from the patient's records and from the records of the model heart is the manner in which the J-wave increases more markedly than the I-wave as the stroke volume returns toward normal. The low J-wave may possibly be a distinguishing mark of a stroke volume below normal.

The other extreme of an unusually large cardiac stroke volume produces also a characteristic pattern, Figure 8. The situation demonstrated is that of aortic insufficiency where the excessively large stroke volume is partly returned to the heart through the faulty aortic valve during diastole. The most striking features of these records are their unusual size (*i.e.*, the I-J slope is extremely steep) under basal conditions as compared with normal records, and the appearance in many records of a slurring in the rising limb of the J-wave. The latter feature was reproducible in the model heart as is also shown in Figure 8. This particular pattern occurs when

FIG. 9

the stroke volume of the model is large and the bulb at the head end of the model is of unusually stretchable rubber.

In Figure 9 are shown several patterns which are dramatically abnormal. The first is a pre-operative iliac arteriovenous fistula in which the fistula carried a large flow of blood. The pattern presents a sequence of footward and headward movements of almost equal size. A possible explanation of this pattern may be that it is the result of a series of impacts due successively to the footward thrust of the ventricular ejection, the headward thrust at the turn of the arch of the aorta, etc., the large footward impact caused by blood changing its direction in passing through the iliac fistula and finally the return to the baseline in time for the cycle to begin again. The post-operative pattern after removal of the fistula shows a slowing of the heart, a decrease in the stroke volume and a restoration of the pattern to a more normal form. In particular the influence of the fistula upon the K-wave should be noted. The second illustration in this figure is a case of constrictive pericarditis. The pre-operative pattern shows a small I-J slope which indicates a stroke volume well below the normal basal value. The post-operative pattern is remarkably improved toward normal and has a normal value of the basal cardiac index.

Figure 10 illustrates changes in the pattern which appear as a result of irregular rhythms of the heart. Part 10 A presents the pattern observed in sinus arrhythmia and shows that the variations are largely in the size of the pattern, the longer filling period being followed by a

steeper I-J slope indicating a larger stroke volume, and the shorter intervals between beats being followed by smaller patterns and therefore

FIG. 10

- A. Irregular beats originating in the sinus node.
- B. Extrasystoles of ventricular origin.
- C. Same patient (B) when extrasystoles are not occurring.
- D. ECG on patient in B and C showing normal and abnormal ventricular patterns.

smaller stroke volumes. Part 10 B illustrates the result of a close succession of beats. The pattern of the premature beat begins before the termination of the pattern of the preceding normal beat and permits only a short filling time. Since this premature beat is not observable in the radial pulse, it is quite possible that the ballistic movement accompanying this beat is not the result of the impact caused by an ejection of blood but is rather an indication of the contribution of the movement of the heart mass to the pattern. Part 10 C shows the ballistic pattern on the same subject at a time when these premature beats are not occurring.

So far in this discussion the presence of the H-wave has been ignored and the movements of the ballistic system considered as beginning with a footward excursion starting at the peak of the H-wave. However, as pointed out by other workers (3), this is probably not correct. For

FIG. 11. BALLISTOCARDIOGRAM OF A PATIENT WITH COMPLETE HEART BLOCK

The auricular complex h, i, j, k is shown as well as the purely ventricular complex I, J, K, . . . Where overlapping of the two complexes occurs, the usual H-wave of the ballistocardiogram appears.

P = beginning of P wave of the electrocardiogram.

Q = beginning of the QRS complex of the electrocardiogram.

h, i, j, k are successive peaks in the auricular complex of the ballistocardiogram.

H, I, J are successive peaks in the normal ballistocardiogram.

PR = the usual interval defined as the time from the beginning of the P wave to the beginning of the QRS complex of the electrocardiogram.

The table above lists the time in seconds between the points so defined.

example, the time interval from the beginning of the QRS complex of the electrocardiogram to the peak of the H-wave is about 0.100 second whereas the time from the QRS complex to the beginning of the ventricular ejection is about 0.0700-0.0800 second (9). Because of this discrepancy, it has been suggested that the I-wave of the ballistocardiogram does not follow the ventricular ejection but rather is associated with some other circulatory event. Of course the possibility exists that the ballistic movements of the

FIG. 12

QH, the time from the beginning of the QRS complex to the beginning of the footward movement producing the I-wave, is plotted against the PR interval, which is taken as an index of the amount of overlapping of the auricular and ventricular ballistic complexes, in a patient with complete heart block.

auricular ejection may act in such a way as to obscure the beginning of the ventricular ejection phase. In order to check this explanation, simultaneous recordings of the ballistocardiogram and the electrocardiogram have been made on several patients having heart block. Figure 11 shows some of the complexes recorded on a patient with complete heart block. The data on the auricular and ventricular complexes are given in Table I. The auricular complex is small and appears to consist successively of a headward (h), a footward (i) and a headward (j) wave of which the average time intervals from the beginning of the P of the electrocardiogram to the peaks of these waves are, respectively, $P_h = 0.10$ second, $P_i = 0.16$ second, and $P_j = 0.24$ second. The purely ventricular complex appears to start directly footward from the baseline with no H-wave in evidence. For this pure ventricular pattern the time from the beginning of the QRS complex to the beginning of the footward movement which produces the I-wave is about 0.070 second, a value which is close to the accepted value for the time from the QRS to the commencement of ventricular ejection. However, this pure ventricular complex is seen only when the PR interval is sufficiently long that the auricular and ventricular complexes do not overlap. This overlap is a function of the PR interval and its effect is illustrated in Figure 12. In this figure the

QH interval (H being the point where the ballistic movement first turns footward) is plotted against the PR interval. When the PR interval is long, the QH interval is about 0.070 second. However, when the PR interval lies within normal range, *i.e.*, from 0.10 to 0.20 second, the QH interval is about 0.090 second. This observation suggests that the auricular j-wave is an important factor in producing the H-wave and in delaying the footward movement of the I-wave. Similarly when the PR interval has a value less than normal the QH interval decreases again. In this case it may be that the footward movement is accentuated by the footward i-wave of the auricular complex. This view that the auricular stroke contributes markedly to the H-wave of the ballistocardiogram is supported by the type of ballistic pattern observed in auricular fibrillation. In this case, see Figure 13, the QH interval is relatively short, 0.060–0.70 second. This value would be expected if the auricular beat was ineffective in moving fluid so that the ballistic movement is almost purely ventricular in origin. As a result of these studies it is concluded that in the ballistocardiograms of normal subjects the auricular impact may act to produce the H-wave and in this action mask the onset of the I-wave.

SUMMARY

In this paper have been presented ballistocardiograph records of clinical cases and of the ejection behavior of a simple model heart. Evidence to support the origin of the K-wave is found in records of coarctation of the aorta and of reactive hyperemia. Characteristic patterns of pre- and post-operative cases of coarctation of the aorta, of constrictive pericarditis and of an iliac arteriovenous fistula are also presented here. Further are shown the form of records with extremely large and small stroke volumes as found respectively in the special conditions of aortic insufficiency and of shock.

Data have been presented from the observa-

FIG. 13. BALLISTOCARDIOGRAM ON A PATIENT WITH AURICULAR FIBRILLATION

tions made on cases in heart block. This material illustrates the contribution of the auricular ejection to the ballistocardiogram and shows that in cases with normal PR intervals the auricular beat may produce an apparent delay in the development of the I-wave, a delay attributed by some workers to faulty behavior of the ballistocardiograph.

ACKNOWLEDGMENT

Acknowledgment is made to the Departments of Medicine and Surgery of Columbia University and of Emory University with whom the collaborative work providing some of the clinical records was performed.

TRANSFERS OF POTASSIUM IN RENAL INSUFFICIENCY¹

By J. RUSSELL ELKINTON,² ROBERT TARAIL,³ AND JOHN P. PETERS

(From the Department of Internal Medicine, Yale University School of Medicine, and the Medical Service of the New Haven Hospital, New Haven)

(Received for publication August 16, 1948)

Elevation in concentration of serum potassium in patients with renal insufficiency has been observed many times but has been considered to be a relatively rare occurrence (1-3). Reports of abnormally low levels of serum potassium in this disorder have been extremely infrequent (4-8). Nevertheless, the occasional finding in such patients of disturbances in the exchanges of potassium, has directed interest toward the clinical significance of these abnormalities.

Winkler, Hoff and Smith were the first to recognize that the toxicity of a high concentration of potassium in serum and extracellular fluid is due to its effect on the conduction system of the heart. In animals rendered anuric by nephrectomy or by ureteral ligation, death regularly resulted from extracellular accumulation, to cardiotoxic levels, of potassium released from tissue cells (9, 10). Such accumulation was speeded by the administration of potassium (10) and retarded by depletion of potassium prior to the establishment of the anuria (11). The potassium content of tissue cells in anuric animals has been shown to vary (12), but experiments in cats indicated that the lethal factor was the elevation of extracellular potassium concentration, not a change in the potassium of the cells (13).

Intolerance of patients with severe renal disease to administered potassium has been recognized in the past (14) and was clearly demonstrated by Winkler, Hoff, and Smith (15). Slight elevations of the serum concentration were found in five of 12 patients studied, but no cardiotoxicity was revealed in electrocardiographic tracings. Since then definite, and possibly fatal, changes in cardiac conduction have been reported in such

patients with high concentrations of serum potassium (16-18).

It is evident, therefore, that in renal insufficiency the concentration of potassium in extracellular fluid may rise, that a number of variables influence the occurrence and rate of such a rise, and that the rise may threaten the life of the patient. Death may also occur in the presence of a normal or low serum concentration and be due to causes quite unrelated to disturbances of potassium metabolism.

The study reported here is an attempt to determine more exactly the frequency of, and the physiological factors involved in, abnormal exchanges of potassium in patients with severe renal insufficiency. The data are presented from the standpoint that abnormality of the concentration of serum potassium in cases of renal insufficiency with reduced glomerular filtration is a function of extracellular fluid volume, intake and output of potassium, and its distribution between the extra- and intracellular phases.

EXPERIMENTAL MATERIAL AND PROCEDURE

During a period of nine months 51 patients had concentrations of blood non-protein nitrogen greater than 100 mg. per cent; in 26 of these patients one or more measurements were made of the concentration of serum potassium. These 26 patients constitute the clinical ma-

* Balances of Cl and Na corrected for small quantities lost in serum drawn for analysis.

† Includes small quantities taken orally, the contents of which were estimated from Sherman's tables (43).

‡ Includes oral liquids in small quantities, which probably contained only small amounts of electrolyte and nitrogen.

§ Includes stool, 75 cc. urine, and 100 cc. vomitus.

** Balances include 550 cc. of vomitus, which contained 75 m.eq. Cl, 45 m.eq. of Na, 8 m.eq. of K, and 1.6 grams of N.

†† Diagnoses are indicated in Table IV.

terial for the survey. They are a selected group in that potassium determinations were more frequently done in patients who were oliguric and in patients who were on the medical service. The concentration of serum potassium was followed with varying frequency and in variable proximity to the time of death. There were many types of kidney disorders responsible for the renal insufficiency in these patients; the diagnoses were made from clinical data, and from necropsy findings when available.

Ten of the 26 patients were studied more intensively. During periods which varied from 12 hours to eight days, exchanges of chloride, sodium, potassium, and nitrogen were measured and the transfers of potassium between the various phases of body fluid were calculated. In some, the volume of distribution and clearance of manni-

tol were determined, to approximate the volume of extracellular fluid and the glomerular filtration rate (19). Electrocardiograms were taken simultaneously with many of the determinations of serum potassium.

The chemical methods and mode of calculation have been detailed in previous communications (20-22).

RESULTS

The analytical and derived data are presented in Tables I-V and in Figures 1 and 2.

The concentration of serum potassium was greater than 5.5 m.eq. per liter in more than one-half the cases; abnormal concentrations were not exclusively associated with any one kind of

In most of the patients the concentration of serum potassium rose as the renal insufficiency progressed (Table III). Distinct decline of serum potassium, as death approached, occurred in at least one patient. In 18 patients concentrations of serum potassium were measured less than 24 hours before death; of these 12 were elevated, four were normal, and two were low. In certain patients changes in the concentrations of blood non-protein nitrogen and of serum potassium varied in similar directions (Table III), but for the group as a whole there was a wide variation

Oliguria or anuria appeared to be a prerequisite to elevation of the serum concentration. None of the patients with concentrations of serum potassium above 6.6 m.eq. per liter produced more than 250 cc. of urine during the preceding 24 hours (Figure 1). On the other hand, periods of anuria or oliguria were not necessarily followed by elevation of serum potassium.

The factors which determine a given concentration of potassium in serum are the volume of extracellular fluid and the amount of extracellular potassium which results from exchanges with the cells on the one hand and the external environment on the other. These exchanges were calculated in detail from the balance data obtained in 10 patients (Tables II and III), and are summarized for nine patients in terms of average

daily values in Table IV. In most of the patients the volume of extracellular fluid expanded. Although the rate of expansion varied considerably, it may have ameliorated any rise in potassium concentration which would have resulted from accumulation of the ion in that fluid phase. In three of the five patients in whom the final concentration of serum potassium was greater than 7.4 m.eq. per liter, the small amount of potassium ingested in food exceeded the urinary output, and the difference, or positive balance, was equal to part or all of the increase in extracellular potassium. In all of the four patients whose final concentrations of serum potassium were less than 6.5 m.eq. per liter, the intake of potassium was negligible and the patients were in negative balance with respect to the ion. A net transfer of potassium from cellular to extracellular phase took place in most of the cases; only in two patients did the cells take up potassium. In four cases in which the ion accumulated in the extracellular phase, the cellular decrement was at least as great as the extracellular increment. If the transfers of intracellular potassium are arbitrarily subdivided into those which move with nitrogen according to cell anabolism or catabolism, and those which enter or leave intact cells, the data indicate that in only two cases did part or all of the potassium from catabolized cells enter intact cells. The storage of potassium by the cells did not appear to be directly correlated with the in-

take of carbohydrate or insulin (Tables II, IV).

Electrocardiograms were obtained from four patients when the serum potassium was greater than 7.4 m.eq. per liter (23). All showed toxic effects of potassium. These patients died suddenly. In one patient, P. DeB., an electrocardiogram was obtained within a few seconds of death. This tracing showed widespread disorganization and prolongation of the QRS complex. Although the concentration of serum potassium was 8.1 m.eq. per liter, it is impossible to assert that it was responsible for the cardiac arrest, as other factors probably play a role in the death of these patients. Other signs and symptoms that have been reported as evidence of potassium intoxication were not observed.

The primary disturbance in these patients was the inability of the kidney to excrete potassium. In comparison with previously reported subjects with normal kidneys, and whose intake of potassium was low (22), the rate of excretion of potassium was lower and the urine:plasma concentration ratio (U/P) was about the same (Figure 2). The rate of excretion and the concentration ratio of potassium were reduced in patients with renal insufficiency when contrasted to normal subjects on an intake high in potassium. Nevertheless, even this limited excretory ability sufficed to prevent an accumulation of potassium in the extracellular fluid when the intake of potas-

‡ Insulin given.

sium was restricted and the oliguria was not extreme.

The rate of glomerular filtration of potassium was reduced far out of proportion to its rate of excretion in two of the three patients in whom the clearance of mannitol was measured. These data, which are presented in Table V with similar data from the control subjects with normal kidneys, permit a distinction between disturbances of glomerular and of tubular function. In these two patients the rate of excretion approached, if it did not exceed, the rate of filtration. The error is so great that this cannot be interpreted as definite evidence of tubular secretion. Nevertheless, the ratio of potassium excreted to that filtered certainly exceeded any such ratios in the control subjects. This was so to a lesser degree with respect to water. Defective glomerular filtration appeared to be the principal factor limiting the excretion of potassium.

The exchanges of potassium were studied in one patient with renal insufficiency with a low concentration of serum potassium (F. S., Tables II and III). During the first day of study sodium was wasted in the urine; the rate of excretion of potassium was within the range found in the potassium-deficient patients with normal kidneys. Since the glomerular filtration rate was probably markedly reduced in this patient the normal excretory rate may have been the result of proportionately decreased tubular reabsorption. Subse-

quently, when potassium was administered it entered the cells and was retained.

DISCUSSION

The results of this study indicate that elevations in the concentration of serum potassium are not infrequent in patients with renal insufficiency. Given the primary difficulty of inadequate renal excretion of potassium, the presence and degree of a rise in the extracellular concentration of the ion depends upon the change in volume of the extracellular fluid, intake of potassium, extrarenal loss of potassium, and net transfer of potassium between the extracellular fluid and the cells. In patients who are anuric and who are receiving parenteral fluids, the extracellular volume may expand. Such a change does not necessarily lower the potassium concentration since it has been shown in experimental animals that expansion of the extracellular volume in itself may lead to transfer of some potassium from the cells (24). Intake of potassium is an important factor in the accumulation of extracellular potassium as the intake readily may exceed the output or rate of excretion. To a certain extent patients are protected against the ingestion of potassium by anorexia, nausea, and pylorospasm (15). But the administration of potassium by any route may jeopardize life, and is clearly contraindicated in any patient with anuria or oliguria.

Extra-renal losses of potassium in gastrointestinal fluid may modify to a limited extent the

extracellular concentration of the ion. But this concentration is probably determined in the main by exchanges of potassium between the extracellular fluid and the cells. In agreement with other observers (25, 26) release of potassium from cells as an agonal or terminal phenomenon due to anoxia, could not be the explanation of the elevated concentration of serum potassium in most of our cases because the rate of rise was not accelerated. On the other hand, potassium was taken up and retained in the cellular phase in only a few of our cases with high extracellular concentrations. This is surprising, since in normal dogs large amounts of potassium can enter cells before being excreted (27), and since others have observed anuric patients to maintain a concentration of serum potassium within the normal range over many days (28). However, these transfers are closely related to the processes of cellular metabolism and in these patients not all of the metabolic variables were known. This fact makes it difficult to predict in a given case the net result of exchanges of potassium between the two fluid phases. The deficit of potassium present in the patients with low serum potassium and renal insufficiency probably resulted from losses of the ion in urine and in gastrointestinal fluid analogous to those observed in potassium depletion associated with normal renal function (22).

There was diminution in the concentration and excretion of potassium by the kidney in the present group of patients. This finding is in agreement with Winkler, Hoff, and Smith (15) and with Keith and Osterberg (29), who found that the clearance of potassium was low in such patients even when potassium was administered.

The rate of glomerular filtration was greatly depressed. In the organism with normal kidneys tubular reabsorption of potassium appears to be, within limits, independent of that of water. During water deprivation the concentration of potassium in urine of the dog may rise to 500 m.eq. per liter, representing a U/P ratio of 80 (30). Increased concentration ratios of lesser magnitude may be inferred from similar experiments on man (31). During water diuresis the excretion rate of potassium may be unaltered and the U/P ratio falls to 1.0 (32). To our knowledge, no U/P ratio of less than 1.0 has been reported (22). When the concentration ratio of potassium exceeds 1.0, it implies that the concentration of potassium in the reabsorbate is less than that of serum. If the concentration ratio of potassium were less than 1.0, the concentration of potassium in the reabsorbate would be greater than that of serum. Tubular secretion of potassium appears to have been demonstrated by Berliner (33) and by Gilman and Mudge (34) under certain experimental circum-

stances. The present data are inconclusive with respect to evidence of tubular secretion.

As predicted by Winkler *et al.* (15), elevation of the concentration of serum potassium was always preceded by oliguria or anuria in our patients. Instances of elevation of serum potassium to toxic levels have been reported in patients who were not oliguric (17), but these patients had received exogenous potassium. In two of the three patients in whom the rate of glomerular filtration was measured, the water excreted was an abnormally large portion of the water filtered, and the potassium excreted approached if it did not exceed the potassium filtered. The restricted excretion of potassium appeared to depend on the reduction of the quantity of potassium filtered. The increase in the ratio of potassium excreted to that filtered proportionately increased the loss of potassium in the urine.

Since depression of the rate of glomerular filtration appears to be the principal limiting factor with respect to potassium in renal insufficiency, the diminished tolerance for administered potassium by such patients is readily explained. The glomerular filtration rate in advanced renal insufficiency may be 10 cc. or less per minute (35); given a normal range of concentration of serum potassium, no more than 50 to 80 m.eq. are filtered per day. Excluding cellular uptake or extra-renal loss of administered potassium, the daily increment of extracellular potassium provided by a normal diet may exceed the amount of potassium filtered. If no potassium is ingested the increment of extracellular potassium due to release of the ion from the cellular phase may not greatly exceed that which can be filtered and excreted.

Aside from restriction of intake of potassium, the treatment of hyperkalemia in the oliguric or anuric patient logically includes measures to counteract its physiological effect, to promote the transfer of potassium into cells, and to produce extra-renal excretion of potassium. The administration of calcium has been shown to antagonize the toxic action of potassium in dogs given infusions of potassium (36). The use of calcium for this purpose in man has been followed by changes in the electrocardiogram (17, 25) but has not yet been thoroughly evaluated. The administration of glucose and insulin to enhance the transfer of potassium into cells was attended with some success

in cases of hyperkalemia due to ischemic muscle necrosis (37). Apparent antagonism of the toxic action of potassium by the administration of glucose and calcium to an infant suffering from potassium intoxication has been reported (38). Glucose and insulin produced no significant effect in our patients, but was not given a sufficiently thorough and systematic trial. Infusion of hypertonic solution of sodium chloride, proposed on the theory that a low concentration of sodium in extracellular fluid leads to shift of potassium from cells, has been reported to produce electrocardiographic and clinical improvement (17). No such relationship is apparent in our data, and the use of hypertonic saline in one case was ineffectual (P. McG.). Treatment with adrenocortical substances has not been successful in animals in which treatment was begun after anuria had been produced (39). Finally, a variety of measures have been proposed to effect the extra-renal removal of extracellular potassium. Dialyses by the artificial kidney of Kolff (40), by peritoneal lavage (41), and by small intestinal lavage (42), have been shown to lower the concentration of certain constituents of blood and serum and may lower that of potassium. These are fairly elaborate procedures, but may prove to have a useful role in combatting potassium intoxication in anuric patients with potentially reversible renal lesions. Such procedures, however, may be secondary in importance to the fundamental therapy of maintenance of volume and composition of the body fluids and of the integrity of the circulation.

SUMMARY

Changes in the concentration of serum potassium were studied in 26 patients with severe renal insufficiency. The serum potassium level was abnormally high in more than one-half of the 26 patients. The greatest elevations were associated with oliguria; but oliguria was not always followed by an elevation in concentration of the ion. In 10 of the patients the intake and excretion of potassium were measured and the distribution of the ion between the cells and extracellular fluid was calculated.

The principal limiting factor in the excretion of potassium was reduction in the glomerular filtration rate.

The serum potassium was depressed in four of the cases; in the one in which it was studied the rate of renal excretion was not abnormally increased.

Potassium was taken up by the cells in only two of the nine cases with hyperkalemia; this process was not clearly accelerated by the administration of carbohydrate and insulin.

Electrocardiographic evidence of intoxication occurred before death in the four patients with serum potassium greater than 7.4 m.eq. per liter.

COMPLEMENT AND ITS COMPONENT FRACTIONS IN CEREBROSPINAL FLUID IN INFLAMMATORY CEREBROSPINAL DISEASES

By SOPHIE SPICER, EMANUEL APPELBAUM, AND DAVID D. RUTSTEIN

(From the Bureau of Laboratories of the Department of Health of the City of New York)

(Received for publication October 9, 1948)

It is generally agreed that normal spinal fluid is entirely devoid of complement, but the reports of its presence in the spinal fluid in cerebrospinal diseases are contradictory. Complement was found in the spinal fluid of all cases of meningococcus meningitis by Ward and Fothergill (1), but was reported to be absent in the same diseases by others (2-4). Ward *et al.* (1, 5) found complement to be absent in the spinal fluid of cases of influenzal meningitis. Hauptmann (6) reported that complement may be found in the spinal fluid of tuberculous meningitis, but not in meningitis of other types. An early report (7) indicated that complement was absent from spinal fluids in various pathological conditions of the central nervous system, including cases with signs of meningitis.

Present evidence indicates that complement activity results from the action of at least four components, more or less loosely combined, and present in different concentrations (8-10). When one or more of these components are missing, there is an absence of complement activity. Since the component in least concentration determines the titer of complement activity (8-10), evidence of such activity will be found when that component is present in minute amounts, and negative results will be obtained when it is entirely absent, although the other three components may be present in considerable quantities. This makes it possible to titrate each of the four components of complement independently by the addition of the other three components in excess. In accordance with the terminology adopted by Pillemer and Ecker (11) and Bier *et al.* (9) for complement and its components, whole complement as demonstrated by hemolytic activity is designated as C' and the four components are designated as C'1, C'2, C'3 and C'4. This evidence has been collected from studies of complement activity in blood serum (8-10). There are no reports of similar studies in human cerebrospinal fluid.

MATERIALS AND METHODS

Definition of reagents. A reagent used for the titration of a given component of complement does not contain the component to be titrated, but contains the three other components. Thus, reagent 1 (R1) contains C'2, C'3, and C'4, but not C'1, and is used for the titration of C'1. Reagent 2 (R2) does not contain C'2, but C'1, C'3 and C'4 and is used for the titration of C'2. Likewise R3 has all the components but C'3, and R4 all the components but C'4, being used for the titration of C'3 and C'4 respectively. Since all four components are required to produce hemolysis of sensitized red blood cells, each of the reagents by itself does not produce hemolysis.

Complement for the preparation of reagents was secured from guinea pigs, which were stunned by a blow at the base of the skull and were bled from the throat into sterile Petri dishes. The blood was left at room temperature protected from light for 30 minutes, and then placed in an icebox overnight. The serum was then drawn off, centrifuged and used immediately. No stored guinea pig serum was used in the preparation of reagents.

Preparation of reagents. With the exception of R3, the methods of preparation of reagents were in general those of Heidelberger and his coworkers, with one major exception. The preparation of zymosan, used by these workers for the inactivation of the third component, is tedious and time consuming. Powdered zymosan, which was used instead, is easy to prepare, yields an excellent reagent and lasts a long time. There were also minor variations in the preparation of the other reagents.

In the separation of complement into R1 (endpiece) and R2 (midpiece) by KH_2PO_4 or CO_2 as carried out in the laboratories of Heidelberger (9) and Ecker (10), the same preparation supplies both the R1 (supernatant fluid) and R2 (precipitate). This routine was varied since a more effective R1 was obtained by one method (KH_2PO_4) and a better R2 by the other method (CO_2).

Preparation of R1. To 9 volumes of chilled M/200 KH_2PO_4 solution 1 volume of chilled guinea pig serum was added slowly with constant mixing. After 20 minutes at 0° C. the mixture was rapidly centrifuged in an angle centrifuge at a speed of 4000 RPM. The supernatant fluid was decanted, made isotonic with 17% NaCl and neutralized with 0.1 N NaHCO_3 . Five ml. amounts of the reagent were measured out into small bottles, tightly plugged, immediately placed in the freezing compartment of the refrigerator and kept in the frozen state until used.

SOPHIE SPICER, EMANUEL APPELBAUM, AND DAVID D. RUTSTEIN

Preparation of R2. A small flask containing distilled water was placed in a beaker full of cracked ice and pure CO₂ gas was allowed to bubble through the water for 30 minutes under slight pressure. One ml. of guinea pig serum was added to 9 ml. of the CO₂ saturated water and CO₂ gas was again passed through the mixture for 20 minutes, keeping the mixture cold. The precipitate formed after 20 minutes' saturation of the serum with CO₂ was rapidly centrifuged in an angle centrifuge at a speed of 4000 RPM, the supernatant fluid was poured off and the precipitate well drained of the fluid by holding a piece of absorbent cotton to the mouth of the inverted tube. The precipitate was then redissolved in 5 ml. of

buffered saline solution. This constitutes R2 and was also stored in the frozen state.

Preparation of R3. Powdered zymine was used in the inactivation of the third component of guinea pig complement. It was prepared as follows: Approximately 5 grams of fresh yeast (Fleischmann's) were placed into a 100 ml. bottle containing 60 ml. absolute alcohol and the mixture was shaken well for 10 minutes. The suspension was then allowed to stand until the large particles settled. Only the very fine particles were collected by careful decanting. It was occasionally necessary to repeat this process to get rid of the coarser particles. The fine suspension was then centrifuged in 50 ml. tubes. The

alcohol was decanted and an equivalent amount of ether added. The suspension was shaken well and centrifuged at 800 RPM with the lid of the centrifuge open. The ether was then decanted and the sediment spread about the inner surface of the tube with a glass rod to facilitate drying. The zymine thus prepared was a fine impalpable white powder, weighing approximately 0.2 gram. If kept in a dry state, preferably over CaCl_2 , it will last for at least three to four months. The number of bottles to be used depends on the amount of zymine desired.

To prepare R3, one gram of powdered zymine was added to 30 ml. of buffered saline, mixed well and placed in a boiling water bath for 30 minutes, being stirred occasionally. It was then removed from the water bath, distributed equally into three 15 ml. centrifuge tubes and centrifuged for five minutes at 1500 RPM. The supernatant fluid was decanted as completely as possible. Each tube then contained the boiled zymine in a volume of about 0.5 ml. One ml. of guinea pig serum was added to each tube, stirred well with a glass rod and placed in a water bath at 37°C . for one and one-half hours. The rods were left in the tubes and used for occasional stirring of the mixture. The serum was then separated from the zymine by centrifugation. It was stored undiluted in the frozen state. Before using, the reagent was diluted 1:5 with buffered saline solution. This solution is stable for at least three to four weeks.

Preparation of R4. To inactivate the fourth component of complement, 0.12 ml. of 0.15 M hydrazine was added to 1 ml. of guinea pig serum, mixed thoroughly and incubated in a water bath at 37°C . for one hour. It was stored undiluted in the frozen state. Before use it was diluted 1:5 with buffered saline.

Titration of complement components. Whenever a sufficient amount of spinal fluid was available, the quantitative method of Wadsworth *et al.* (13) was used as in previous studies (14, 15). However, in the majority of cases only enough fluid was obtained to enable us to apply a qualitative test as follows: The presence of complete hemolysis of 0.2 ml. of a 5% suspension of sensitized sheep's red blood cells in 0.15 ml. of spinal fluid was read as 100% hemolysis. Partial hemolysis was read by comparison with color standards (13) representing percentages of hemolysis ranging from 5% to 95% in intervals of 5%.

Spinal fluid specimens. The spinal fluids used in this study were those collected by the Division of Acute Infectious Diseases of the Central Nervous System of the Bureau of Laboratories of the New York City Department of Health. These specimens were routinely examined for total protein, sugar content, cell count and the presence of micro-organisms, and the results were made available for comparison with titers of complement activity.¹

A total of 43 specimens were examined from 43 cases of cerebrospinal diseases, including cases of meningitis caused by the pneumococcus, meningococcus, *beta* hemolytic streptococcus, influenza bacillus, tubercle bacillus, as well as from cases diagnosed as poliomyelitis, measles encephalitis, postvaccinal encephalitis, mumps encephalitis, encephalomyelitis and other diseases as indicated in Tables I and III. All specimens were tested within 72 hours of collection, and the majority were tested within 24 hours of collection. All specimens were kept at refrigerator or freezing temperatures during the interval. From previous observations on blood serum (15), it is unlikely that the delay between collection and testing was a factor in the results obtained.

TABLE II

Median concentration of spinal fluid sugar and protein according to complement components present

Complement components present*	Number of cases	Median protein conc. (mg./100 ml.)	Median sugar conc. (mg./100 ml.)
Large	7	259	12
Moderate	15	82	29
Small	17	39	56

* Large = All four components present (complement activity).

Moderate = Three components present.

Small = Two or one components present.

It would have been desirable to test for complement components in every specimen of spinal fluid from each patient so as to follow the exact trend of the appearance and disappearance of individual components during the course of disease. This study was limited, however, to individual observations during the disease because of the method of collection of specimens. Nevertheless, the data as collected adequately support the conclusions reached in this paper.

In most instances, spinal punctures were performed by hospital internes and the specimens sent to the Bureau of Laboratories by messenger. The amount of spinal fluid necessary for the performance of routine examinations was removed, and the remainder forwarded for complement titration.

RESULTS AND DISCUSSION

Table I, consisting of analyses of single specimens from individual cases of meningitis, demonstrates the correlation of the changes in complement activity with those in protein and sugar concentrations. The greater the deviation of the routine laboratory findings from normal, the greater the number and the concentration of the individual components. This is further demonstrated in Table II. Thus complement titrations,

¹ Acknowledgment is made to Miss Ruth Gosling, Bacteriologist, Bureau of Laboratories, New York City Department of Health, who performed the routine examinations.

cerebrospinal fluid, during acute inflammatory diseases, results from leakage of the components across the membrane of the choroid plexus, and not from local production of the individual components; however, proof of this must await simultaneous titrations of specimens of blood and cerebrospinal fluid.

SUMMARY

1. One or more components of complement were always found in the spinal fluid in infectious cerebrospinal disease.

2. In specimens from patients with infections of the central nervous system, an analysis of the number and concentration of the components correlates with the median values of abnormal concentrations of protein and sugar.

3. In specimens obtained from cases of inflammatory diseases of the central nervous system not due to bacteria, the number and concentration of the components are less than those occurring in the bacterial diseases.

4. In inflammatory diseases of the central nervous system, C'4 and C'1, the components present in largest concentration, occur most frequently. C'3 and C'2 follow in order of occurrence and in concentration.

5. C'2 is found in least frequency and then only in low titer. It is this component which determines total complement activity of the cerebrospinal fluid, since it is only found when the other three components are present.

ACKNOWLEDGMENT

The technical assistance of Miss Diana Blitz is gratefully acknowledged.

THE EFFECT OF ADRENOCORTICOTROPHIC HORMONE IN CONGENITAL ADRENAL HYPERPLASIA WITH VIRILISM AND IN CUSHING'S SYNDROME TREATED WITH METHYL TESTOSTERONE¹

By ROGER A. LEWIS AND LAWSON WILKINS

(From the Department of Pediatrics, Johns Hopkins University School of Medicine, and the Harriet Lane Home of the Johns Hopkins Hospital, Baltimore)

(Received for publication October 13, 1948)

There have been several reports of the metabolic effects of adrenocorticotrophic hormone in normal individuals (1-3) and in patients with Addison's disease (1), or panhypopituitarism (4). This trophic hormone has little or no effect upon the metabolic processes in Addison's disease. In normal individuals and in cases of panhypopituitarism there may be profound effects. The changes which occur in the first four hours after a single injection of 25 mg. have been studied by Thorn and his coworkers (1). The hematological changes consist of a shift from mononuclear to polymorphonuclear cells and a fall in the number of eosinophils. The metabolic changes are reflected in the urinary excretion. Using creatinine as a reference there is a rise in uric acid, potassium, chloride and sodium.

Browne and his group (2) have studied the effect of large doses, 210 mg., of adrenocorticotrophic hormone administered over a 24-hour period to a normal patient. They found oliguria, weight gain, increased excretion of 17-ketosteroids and neutral reducing lipids, increased excretion of potassium and retention of sodium and chloride. The retention of sodium was apparent during the 24 hours of treatment and more marked during the 24 hours immediately after treatment. There was also an increase in the fasting blood sugar from 98 to 148 mg. %, glycosuria and a slight rise in the urinary output of nitrogen.

The effect of long range treatment with adrenocorticotrophic hormone has been studied by Thorn and his group, 40 mg. a day for four to six days (1); by Mason *et al.*, 25-100 mg. a day for 12

days (3); and by Albright, Forbes and Bartter, 100 mg. a day for six days (4). Mason *et al.*, working with Li's hormone isolated from sheep glands, noted an increase in the excretion of 17-ketosteroids and neutral reducing lipids but no significant alteration in electrolyte metabolism. However, Thorn's group and Albright, Forbes and Bartter, working with adrenocorticotrophic hormone isolated from hog pituitaries, noted in all cases an increase in the excretion of potassium and decrease in the excretion of sodium and chloride during the administration of the hormone. Although the retention of sodium and chloride was more marked during the second 24 hours of treatment it also occurred consistently during the first 24 hours. Other changes were a rise in the excretion of 17-ketosteroids and neutral reducing lipids, a rise in the fasting blood sugar and an increased excretion of nitrogen. Albright, Forbes and Bartter studied also the effect of adrenocorticotrophic hormone isolated from sheep glands and observed the same effects as with the hog gland preparation.

There have been no reports on the effect of adrenocorticotrophic hormone upon the respiratory quotient and no studies upon its effect in Cushing's syndrome or adrenal hyperplasia with virilization. During the past year we have been able to administer adrenocorticotrophic hormone to one patient with Cushing's syndrome who was being treated with methyl testosterone, and to two girls with congenital adrenal hyperplasia causing pseudohermaphroditism. Studies of the respiratory quotient as well as other metabolic effects and the renal excretion of steroids and electrolytes were performed. The results were quite unusual and despite the small number of cases studied are being reported at this time.

METHODS

The patients were placed on a constant diet which approximated the normal intake as closely as possible.

¹ This work was made possible by a grant from the American Cancer Society for studies on the relationship of the pituitary hormones, thyroid hormone and the steroid hormones of the adrenal glands and gonads to normal and abnormal growth, and by a grant from the Commonwealth Fund for the study of endocrine problems in childhood.

TABLE I
Composition of the diet

Syndrome	Carbo- hydrate	Fat	Pro- tein	Calo- ries	Sod- ium	Potas- sium	Chlo- ride
	gm.	gm.	gm.	cal.	m.eq.	m.eq.	m.eq.
Cushing's syndrome	265	90	90	2,200	80	106	70
Adrenal hyper- plasia case B	220	80	60	1,800	126	85	100
Adrenal hyper- plasia case D	225	80	60	1,800	112	84	100

The protein, fat and carbohydrate composition of the diet as well as the sodium, potassium and chloride content were calculated from conventional sources. Each patient was given one gram of salt a day to use in seasoning food. This is included in the figures for the diet presented in Table I. The fluid intake was not restricted because of the variable warm weather.

Venous blood was taken for chemical and hematological studies 24 hours before the start of treatment, 48 hours later at the end of the 24-hour treatment period, and again 48 hours later. The respiratory quotient and metabolic rate were determined before breakfast and in the afternoon following a rest period of two to three hours. Urine was collected in 24-hour periods and preserved with thymol and acetic acid.

No studies were made during the first three days on the constant diet. The next three days served as a control period and treatment was given over the next 24 hours. The following 24-hour period was kept separately

to see if there was any carryover or rebound from the treatment period. The following three days served as a post-treatment control period.

The gas analyses were made with a Scholander apparatus (5) on samples of expired air collected in a Douglas bag. Ketosteroid excretion was measured by colorimetric estimation with dinitrobenzene in alkaline alcoholic solution (6). The neutral reducing lipids of the urine were measured by the phosphomolybdic acid color reaction (7) performed on extracts obtained by chloroform extraction and subjected to benzene-water partition (8) but not Girard's separation.² Other chemical determinations were performed by conventional methods (9) except for sodium and potassium which were estimated with the flame photometer (10). Ordinary technics were used in the hematological studies.

The adrenocorticotrophic hormone used in these experiments was prepared from hog pituitary glands.³ Each patient was given eight intramuscular injections of 66 mg. hormone freshly dissolved in 5 cc. of normal saline at intervals of three hours. The total dose of 528 mg. was equivalent to 83 mg. of the standard preparation as assayed by the manufacturers.⁴

CASE HISTORIES

Cushing's syndrome: The patient (H. L. H. A 35977) was a boy aged 16½ years. His health was excellent

² The neutral reducing lipids are generally reported as "11-oxysteroids."

³ Kindly furnished by Dr. John R. Mote, The Armour Co., Chicago, Illinois.

⁴ Lot No. 42-B, serial No. G-59703-A, 33 mg. equivalent to 5.2 mg. standard.

until the present illness which began at the age of 11 when he was a thin and energetic child. In the course of the next year he gained 50 lbs., developed a round "moon" ruddy face, purplish striae on the trunk, acne and excessive hair. The glucose tolerance was of a diabetic type but glycosuria did not occur. His blood pressure was 160/100. X-rays showed osteoporosis and a calculus in the right kidney. At the age of 12 a right ureterolithotomy and a left nephrolithotomy were performed. The adrenals were explored and found to be grossly normal. A biopsy showed hyperplasia of the

reticular zone of the cortex. He was given 20 doses of 95 R.U. of radiation to the pituitary. In 1945 at the age of 14 he was readmitted and found to have a urinary excretion of 2.9 mg. of neutral reducing lipids and 27-37 mg. of 17-ketosteroids. He was then placed on 30 mg. methyl testosterone daily and the neutral reducing lipids fell to 0.58 mg., while the 17-ketosteroids fell to 12 mg. Treatment with methyl testosterone was continued up until the time of the present study, throughout the experiment and after discharge from the hospital. At the time of these studies the classical picture of Cushing's

syndrome had not changed materially although there had been no apparent progress of the disease. The weight was 133 lbs. and the height 55.3 inches. Obesity and dull red striae were still present. The blood pressure was 150/100. The testes measured only 1.8×3 cm. X-rays showed a bone age of 15 years and slight osteoporosis. The laboratory data are given in Tables II-V.

Congenital adrenal hyperplasia with female pseudo-hermaphroditism. Case B. The patient (H. L. H. A 47344) was a girl aged $6\frac{1}{2}$ years. Mother, father and a younger sister are alive and well. General health excellent except for the present illness and an attack of measles one month before this hospitalization. Enlarged clitoris and absence of a vaginal orifice was noted at birth and pubic hair appeared at the age of three. At five she was found to have a height age of seven and a bone age of 11 with an I.Q. of 120. The clitoris was amputated and a urogenital sinus was demonstrated. At the time of these studies the weight was 63 lbs. and the height 56 inches. There was abundant pubic and axillary hair and the voice was deep. There was marked acne and seborrhea. The laboratory data are shown in Tables II-V.

Congenital adrenal hyperplasia with female pseudo-hermaphroditism. Case D. The patient (H. L. H. A 30453) was a girl aged $6\frac{1}{2}$ years. Mother and father are well and a younger sister is quite normal but two younger brothers have adrenal hyperplasia with precocious secondary sexual development but small testes. At the age of 12 days a diagnosis of pseudohermaphroditism was made. At the age of 19 months a urogenital sinus was demonstrated and a laparotomy performed. This revealed normal uterus and ovaries and normal sized adrenals. At the age of five years pubic hair appeared. At the time of these studies the weight was 59 lbs. and the height 55.5 inches. There was abundant pubic and axillary hair and the voice was unusually deep. There was no pigmentation although the skin was tan

in color. Laboratory examinations are shown in Tables II-V.

RESULTS

From Table II it may be seen that there was very slight rise in the blood pressure of the two cases of adrenal hyperplasia, and no rise in the case of the treated Cushing's syndrome until the day after treatment was completed. There was little change in the pulse rate and no febrile response. The girls with adrenal hyperplasia lost .3 to .4 kg. of weight during the 24-hour treatment period while the boy with Cushing's syndrome gained approximately the same amount, .3 kg. The fluid intake was not constant nor accurately measured. There was no consistent change in the metabolic rate of the girls with adrenal hyperplasia, while there was a slight rise in the case of Cushing's syndrome.

The rise in excretion of neutral reducing lipids, Table III, in the cases of adrenal hyperplasia was small, from .27 to .37 mg. per 24 hours in one case, and from .14 to .30 mg. per 24 hours in the other, while in the case of Cushing's syndrome the rise was more marked and lasted longer. It averaged .33 during the control period and rose to 1.06 on the day of treatment, remained at .69 the next day and then averaged .33 mg. per 24 hours for the next three days. The fall in respiratory quotient in the cases of adrenal hyperplasia was also less marked than in the case of Cushing's syndrome. In the latter, the respiratory quotient dur-

ing the control period averaged .85, immediately after treatment fell to .76, rose to .89 the next day and then averaged .90 the next three days.

There was no rise in the fasting blood sugar in the cases of adrenal hyperplasia, but in the boy with Cushing's syndrome the fasting level of 76 mg. % was increased to 116 mg. % after the injection of adrenocorticotrophic hormone, and fell again the next day to 80 mg. %, Table IV. The urinary excretion of nitrogen remained relatively constant except in one of the cases of adrenal hyperplasia where there was an increase on the day of treatment.

Although the daily excretion of 17-ketosteroids before treatment was much higher in the girls with adrenal hyperplasia and virilism than in the case of Cushing's syndrome, following adrenocorticotrophic hormone there was also a greater rise in the urinary output, *i.e.*, from 27 to 42 mg. in one case, and from 32 to 55 mg. in the other. The rise in the case of Cushing's syndrome persisted for a longer time, the excretion being 10.4 mg. daily during the control period, 24.4 on the day of treatment, 20.2 the next day and then averaging 8.3 mg. for the next three days.

There was a moderate increase in the excretion of potassium on the day of treatment in the case of Cushing's syndrome and in one of the cases of adrenal hyperplasia. All three cases showed a decreased potassium excretion on the day following treatment.

The boy with Cushing's syndrome showed a very marked retention of sodium on the day of treatment, an effect which carried over to the next day. The sodium excretion during the control period averaged 142 m.eq. per day, fell to 39 m.eq. on the day of treatment, remained at 38 m.eq. the next day, and then rose to 133 m.eq. a day for the last three days of the experiment. This retention of sodium was so marked that there was a decrease in the chloride excretion despite the rise in potassium excretion.

On the other hand, both cases of adrenal hyperplasia with virilism showed an increased excretion of sodium on the day of treatment. In one of the cases the sodium excretion rose from 138 m.eq. a day to 468 m.eq. on the day of treatment and dropped to 81 m.eq. a day for the following four days. With the increased sodium excretion there was also an increase in the chloride excretion. The

girl who showed the marked sodium and chloride diuresis manifested a slight drop in serum sodium and chloride, from 137.5 to 135.5 m.eq. per l. and from 104.0 to 102.0 m.eq. per l. respectively.

Only in the case of Cushing's syndrome was there a significant change in the serum cholesterol which fell from 375 to 327 mg. %, and then rose to 345 mg. %. In this case the total serum fat also fell from 1120 to 1070 mg. %, and then rose to 1250 mg. %.

All three cases showed a slight rise in the total white blood cell count and a shift from mononuclear to polymorphonuclear cells, Table V. The boy with Cushing's syndrome manifested a fall in the percent of eosinophils at the end of the treatment period, while the two girls showed a delayed rise in the eosinophil count when it was taken during the post treatment period. The eosinophil percentage was determined by blood smears rather than by direct count so that minor changes are not significant.

DISCUSSION

The boy with treated Cushing's syndrome responded to the injections of adrenocorticotrophic hormone in much the same fashion as a normal individual (1, 2). The rise in 17-ketosteroid and neutral reducing lipid excretion was of approximately the same magnitude and duration (two days) as with normal individuals. It should be noted at this point that this patient had received pituitary radiation in the past and was given 30 mg. methyl testosterone daily for two years prior to hospitalization. This medication was continued throughout the experiment. Whether this patient was in partial remission or merely kept under control by the administration of methyl testosterone cannot be determined with certainty.

The sodium retention and gain in weight despite the potassium diuresis are similar to the phenomena which occur in normal individuals given adrenocorticotrophic hormone.

The increase in fasting blood sugar observed in this case is similar to that reported in normal individuals although in this instance glycosuria did not occur. McAlpine has pointed out that when glycosuria is produced the excretion of glucose is greater than could be accounted for by the increased excretion of nitrogen so that he suggested that the adrenocorticotrophic hormone might pro-

duce a decrease in the oxidation of glucose as well as an increase in the amount of gluconeogenesis (2). The fall in respiratory quotient observed in this case of Cushing's syndrome following the administration of adrenocorticotrophic hormone suggests that there may have been a decrease in the utilization of glucose or a relative increase in the utilization of fats.

The effects of adrenocorticotrophic hormone in the cases of congenital adrenal hyperplasia with pseudohermaphroditism differ in certain respects from those found by us in the patient with Cushing's syndrome, or those reported in normal and hypopituitary individuals. In the cases of adrenal hyperplasia of the androgenic type, this hormone caused a moderate or marked increase in the renal excretion of sodium instead of a sodium retention which is usually found. It is believed that this represents the first clearcut example of a trophic hormone producing a qualitatively different effect upon the same endocrine gland and suggests that the secretory activity of the adrenal in cases of congenital adrenal hyperplasia with virilism differs qualitatively from that of other conditions.

The explanation of the sodium loss is not entirely clear. In a preliminary discussion (11) it was suggested that in patients with congenital adrenal hyperplasia associated with Addisonian crises the adrenal glands might secrete steroids which promote sodium excretion rather than sodium retention. It is known that the compounds 17-hydroxycorticosterone and 17-hydroxy-11-dehydrocorticosterone promote the excretion rather than the retention of sodium (12). The fact that adrenocorticotrophic hormone did not cause as great a rise in the excretion of neutral reducing lipids in the cases of adrenal hyperplasia with virilism as it did in the case of Cushing's syndrome does not prove or disprove this hypothesis. The marked increase in the production of 17-ketosteroids is compatible with the fact that the clinical findings in these cases are principally due to excessive androgen.

SUMMARY

Adrenocorticotrophic hormone, equivalent to 83 mg. of the standard preparation, was administered over a 24-hour period to one case of Cushing's syndrome being treated with methyl testosterone

and two cases of congenital adrenal hyperplasia with virilism.

The Cushing's syndrome showed a rise in the renal excretion of 17-ketosteroids and neutral reducing lipids, a rise in the fasting blood sugar, a fall in the respiratory quotient, a polymorphonuclear leukocytosis, an increase in the excretion of potassium and a marked reduction in the excretion of sodium accompanied by a slight temporary gain in weight.

The two cases of congenital adrenal hyperplasia with virilism showed a marked rise in the renal excretion of 17-ketosteroids and only a slight rise in the renal excretion of neutral reducing lipids. There was no rise in fasting blood sugar, slight fall in the respiratory quotient, and a polymorphonuclear leukocytosis. There was a moderate to marked increase rather than decrease in sodium excretion with a slight temporary loss rather than gain in weight.

ACKNOWLEDGMENT

The assistance of Miss Lee Helfgott and Miss June Hunt in performing the steroid determinations is gratefully acknowledged.

The assistance of Dr. R. L. McLean and Miss M. E. Keavney who performed the gas analyses is gratefully acknowledged.

The assistance of Mr. H. Eisenberg in performing the sodium and potassium determinations is also gratefully acknowledged.

A BRIEF SKETCH OF THE HISTORY OF THE AMERICAN SOCIETY FOR CLINICAL INVESTIGATION

ASSEMBLED FROM ITS RECORDS BY

J. HAROLD AUSTIN, M.D.

(The William Pepper Laboratory of Clinical Medicine of the University of Pennsylvania)

The American Society for Clinical Investigation as it is now known was organized in 1908 under the name: The American Society for the Advancement of Clinical Investigation. The present name was adopted in 1916.

The story of its organization has been preserved for us by Dr. Henry A. Christian in the opening pages of the first Minute Book.

FROM THE FIRST MINUTES OF THE SOCIETY

"At the time of the meeting of the American Medical Association at Atlantic City in June, 1907, several men met in an informal conference to discuss the advisability of the organization of a society whose prime purpose should be the encouragement of medical research in this country by men engaged actively in the practice of medicine.

"As a result of this meeting a committee was organized which met at the University Club in Boston on June 17, 1907, with Dr. D. L. Edsall of Philadelphia and Drs. Wilder Tileston, J. H. Pratt, and H. A. Christian of Boston present. The general scope of the society was discussed at this time and it was decided to include in the committee Dr. W. T. Longcope of Philadelphia, Dr. Rufus Cole of Baltimore and Dr. S. J. Meltzer of New York, all of whom had been present at some of the informal discussions at Atlantic City. It was decided that a meeting should be held in New York City before the meeting of the Interurban Clinical Club for further consideration of the advisability of the organization of such a society, and before this meeting was held the committee was increased by the addition of Dr. J. A. Capps of Chicago and Dr. A. W. Hewlett of San Francisco. The names of a number of men considered eligible for membership in the society were divided between the members of the committee in order that a list of their publications during the past five years might be looked up and thus form the basis of determination of their suitability to be asked to take part in the organization of the society. It was agreed that seven of the nine members of the committee must approve each man before he could be considered eligible to receive a notice explaining the aims and objects of the society and inviting him to be present at the meeting for organization.

"On November 7, 1907, a second meeting of the committee was held at the Manhattan Hotel, New York, with Drs. Meltzer, Edsall, Cole, Capps, Pratt, Longcope, Tileston and Christian present. It was decided to have

the organization meeting of the society on the day previous to the meeting of the Association of American Physicians in Washington. A committee of three to draft a constitution for presentation at the meeting of organization was appointed as follows—Dr. W. T. Longcope, Dr. S. J. Meltzer and Dr. H. A. Christian.

*New Willard Hotel, Washington, D. C.
May 11, 1908*

"At 3:30 p.m. the following gentlemen: Drs. D. L. Edsall, S. J. Meltzer, A. W. Hewlett, Wilder Tileston, E. Libman, J. A. Capps, T. C. Janeway, W. J. Calvert, J. L. Miller, J. Sailer, Martin Fischer, E. A. Locke, and Mark Richardson, met in response to a letter of invitation sent out by a committee composed of the following: D. L. Edsall, H. A. Christian, S. J. Meltzer, J. H. Pratt, W. T. Longcope, Rufus Cole, Wilder Tileston, J. A. Capps, and A. W. Hewlett, for the organization of a new society whose proposed scope had been outlined in a circular letter.

This meeting was called to order by Dr. D. L. Edsall of Philadelphia.

"Dr. Edsall was then elected temporary chairman; Dr. H. A. Christian of Boston, temporary secretary.

"The meeting proceeded to the consideration of the Constitution prepared by its committee, and with a few modifications of this adopted it as the original Constitution. Officers and Council to serve through the first Annual Meeting were elected.

"The charter members were:

Ashford, B. K., U. S. Army
Baldwin, E. R., Saranac Lake
Calvert, W. J., Columbia, Mo.
Capps, J. A., Chicago
Christian, H. A., Boston
Cole, Rufus, Baltimore
Cowie, D. M., Ann Arbor
Edsall, D. L., Philadelphia
Emerson, C. P., Baltimore
Emerson, Haven, New York
Fischer, Martin, San Francisco
Foster, N. B., New York
Hewlett, A. W., San Francisco
Howland, John, New York
Hunt, J. R., New York
Janeway, T. C., New York
Libman, E., New York
Locke, E. A., Boston
Longcope, W. T., Philadelphia
McCarthy, D. J., Philadelphia

Meltzer, S. J., New York
 Musgrave, W. E., Manila, P. I.
 Pratt, J. H., Boston
 Richardson, M. W., Boston
 Rosenow, E. C., Chicago
 Sailer, J., Philadelphia
 Simon, Charles E., Baltimore
 Steele, J. D., Philadelphia
 Strong, R. P., Manila, P. I.
 Tileston, Wilder, Boston
 Wallace, G. B., New York."

The Constitution with its eight amendments is given here, for in the printed copies only the Constitution as amended up to 1916 is to be found so that the early form tends to be lost from sight. The first printed copy in 1916 substituted the first three amendments adopted in 1911, 1913 and 1916, respectively, for the original form of these parts.

When in 1924 the next amendment was adopted it was designated as Amendment I and subsequent amendments have been successively numbered. It was probably forgotten that three prior amendments had been made.

THE AMERICAN SOCIETY FOR CLINICAL INVESTIGATION CONSTITUTION

ARTICLE I. NAME

The name of this organization shall be "The American Society for the Advancement of Clinical Investigation."

[See Amendment (1916).]

ARTICLE II. OBJECTS

The objects of this Society shall be the cultivation of clinical research by the methods of the natural sciences; the unification of science and practice of medicine; the encouragement of scientific investigation by the practitioner and the diffusion of a scientific spirit among its members.

ARTICLE III. MEMBERSHIP

Section 1. *Eligibility.*

Any practicing physician residing in the United States or Canada who has accomplished a meritorious, original investigation in the clinical or allied sciences of medicine, and who enjoys an unimpeachable moral standing in the medical profession, is eligible to membership.

Section 2. *Obligations.*

Members must manifest a continuous interest in the objects of the Society (1) by carrying out and

reporting some original investigation in medicine at least once in three years; (2) by attending at least every other annual meeting. The neglect of either of these two obligations without an explanation acceptable to the Council carries with it forfeiture of membership. (3) By being active in the diffusion of the principles of the Society, particularly among the students who come under their charge.

[See Amendment IV (1939).]

Section 3. *Nominations and elections.*

Nominations to membership signed by two members who are not officers of the Society must be made in writing at an annual meeting of the Society, and within three months after the time of nomination the nominators shall transmit to the Council letters stating the qualifications of the nominee and also a list of his professional positions and publications. The Council shall report those nominations which are approved by a two-thirds vote to the next annual meeting for election. An affirmative vote of three-fourths of the members present shall be necessary for the election of members.

[See Amendment (1913-15).]

Section 4. *Expulsion.*

Members may be expelled also for reasons not especially mentioned in the Constitution by a three-fourths vote of the total membership. The vote shall be by secret ballot.

[See Amendments I(1924), II(1929), III(1930), V(1941).]

ARTICLE IV. OFFICERS

Officers of the Society shall be a President, Vice-President, Secretary, and Treasurer, all to be elected as follows: each year a Councillor shall be elected to serve three years. However, at the first meeting three Councillors shall be elected, one of whom shall serve one year, one two years and one three years. The order of retirement of the first Councillors is to be determined by lot. A retiring officer, with the exception of the Vice-President, the Secretary and the Treasurer, shall not be eligible for any office until the expiration of one year. These officers are to be nominated by a committee of three appointed by the President, and the election shall be by secret ballot.

[See Amendment (1911).]

ARTICLE V. DUTY OF OFFICERS

The duties of President, Vice-President, Secretary, and Treasurer shall be those usually assigned to those officers. The Secretary shall also arrange for the publication of abstracts of papers presented at the meetings of the Society.

ARTICLE VI. COUNCIL

Council shall consist of the President, Vice-President, Secretary, Treasurer, and the three Councillors. Four members shall constitute a quorum. It shall be the duty of the Council to supervise the affairs of the Society, to make all the arrangements for the annual meeting, to report on the work of the members, to consider all nominations for membership and to report on them at the meeting at which they shall be balloted on.

ARTICLE VII. MEETINGS

The Society shall hold one general meeting annually.

ARTICLE VIII. QUORUM

Any number of members at the appointed time of the annual meeting shall constitute a quorum for the transaction of ordinary business. For the election of members, fifteen shall be necessary for a quorum, and for altering the Constitution forty per cent of the membership shall be necessary.

ARTICLE IX. ANNUAL DUES

The annual dues of the Society shall be such sum as the Council from time to time may fix. The non-payment of dues for three consecutive years carries with it the forfeiture of membership.

ARTICLE X. AMENDMENTS TO THE CONSTITUTION

Amendments to the Constitution must be proposed in writing by five members at an annual meeting, and must be acted upon at the succeeding annual meeting, notices of which shall contain an announcement of the proposed amendment, and such amendments shall require for their adoption an affirmative vote of three-fourths of those present.

AMENDMENTS

1911: Article IV amended to read:

ARTICLE IV. OFFICERS

Officers of the Society shall be a President, Vice-President, Secretary, and Treasurer, all to be elected annually. In addition each year a Councillor shall be elected to serve three years.

However, at the first meeting three Councillors shall be elected, one of whom shall serve one year, one two years, and one three years. The order of retirement of the first Councillors is to be determined by lot. All officers are ineligible for re-election except the Secretary and Treasurer, who may be re-elected twice, the total period of continuous service not to exceed three years. These officers are to be nominated by a committee of three appointed by the President, and the election shall be by secret ballot.

1913 (with confirmation 1915): Article III, Section 3, to read:

Section 3. *Nominations and election.*

Nominations to membership may be made in writing to the Secretary at any time. Nominations must be signed by two members, who are not officers of the Society, and must be accompanied by a statement of the qualifications of the nominee and a list of his professional positions and publications. All names thus placed in nomination prior to January 1st preceding each annual meeting shall be considered by the Council, which shall pass upon the qualifications of the candidates and report to the Society for election at the annual meeting such names as it shall approve by a two-thirds vote. An affirmative vote of at least three-fourths of the members present shall be necessary for election.

The Council shall also report to the Society a list of candidates whose names shall be continued in nomination.

1916: Article I amended to read:

ARTICLE I. NAME

The name of the Society shall be "The American Society for Clinical Investigation."

1924: Amendment "I": add to Article III:

That the number of active members be limited to 200. Active members whose membership has extended throughout twenty years, will automatically be transferred to emeritus membership, and those whose membership has extended throughout ten years or more may at their own request be

transferred by the Council to emeritus membership.

[See Amendments III (1930) and V (1941).]

1929: Amendment "II": add to Article III:

In addition to the classes of membership already provided, there shall be a class of associate memberships each open upon recommendation of the Council to universities, to clinics or to other organized groups and each to continue from year to year by the approval of the Council. The dues of such memberships are to be such sums as the Council from time to time may fix and these dues shall be used for the support of the Journal of Clinical Investigation. Such memberships shall be without voting privilege.

1930: Amendment "III": amending Amendment I (1924) adding:

Active members who have reached the age of forty-five years prior to the annual spring meeting of the Society, shall automatically become emeritus members.

1939: Amendment "IV": amending Article III, Section 2, to read:

Section 2. *Obligations.*

Members must manifest a continuous interest in the objects of the Society by the following: (1) They must attend at least every other annual meeting. The neglect of this obligation without an explanation acceptable to the Council carries with it forfeiture of membership. (2) They must be active in the diffusion of the principles of the Society, particularly among the students under their charge.

1941: Amendment "V": amending Amendment I (1924):

(a) Active members, whose membership has extended throughout twenty years, will automatically be transferred to emeritus membership, and those whose membership has extended through ten or more years may at their own request be transferred by the Council to emeritus membership. [See also Amendment III (1930).]

Emeritus members shall be entitled to attend all meetings, but not to vote or hold office. They shall be exempt from dues.

(b) The Council shall have authority to recommend each year to the Society the names of properly qualified candidates equal to the number of retiring active members, or up to the number of twenty-five, depending on which number is the larger.

At the first Annual Meeting in Washington in 1909 there were 15 of the 31 charter members present. On the program were listed 16 papers including the President's address: of these 13 are recorded as having been read.

At this meeting the first President, Dr. S. J. Meltzer, outlined in his opening address the purposes for which the Society was formed. No better statement can be made than this address provides. It can be read in full in the Journal of the American Medical Association. Excerpts from it are presented here:

EXCERPTS FROM THE PRESIDENTIAL ADDRESS AT THE
FIRST ANNUAL MEETING OF THE AMERICAN
SOCIETY FOR THE ADVANCEMENT OF CLINICAL INVESTIGATION, MAY 10, 1909,
WASHINGTON, D. C.

(From J. A. M. A., 1909, 53, 508-512)

"The honor of the presidency of a society goes with the privilege of discussing some of the aims of that society. Such a privilege becomes a duty on the occasion of its first birthday. We have to show the specificity of our objects to justify the addition of a new medical society to the many already in existence. As your first president and as one of the instigators of the movement which led to the formation of this association permit me to discuss some of the problems to the solution of which this association wishes and hopes to contribute.

CLINICAL MEDICINE AS A SCIENCE

"In the first place, I wish to discuss the problem of clinical medicine as a science. In years gone by, medicine was a unit and its leaders tried to master all its aspects. With the development of scientific methods and the growth of knowledge a process of differentiation took place. Heavy branches grew out of the stem of medicine, broke off and obtained an independent existence. Anatomy with all its dependencies broke away early, then followed physiology, pathologic anatomy, pharmacology and physiologic chemistry. Bacteriology tore off the branches of etiology and established itself as an independent growth. All these offsprings of medicine are

now well established as pure sciences, they still closely affiliate with the mother-stem and are often designated as the sciences of medicine. What is left of the old stem is clinical medicine. What is the character of this residuum? It is generally designated as the practice of medicine. I am not aware that any one has had the courage to call it a pure science. Those who do not like to call it an art say that it is an applied science. According to this view, the relation of clinical medicine to the sciences of medicine is that of technology to science in general. I am afraid that this conception of clinical medicine is widespread among those who are in the practice as well as among those who are in the sciences of medicine.

"However this may be, I feel sure that such a view is logically erroneous and practically harmful. I wish to plead for an extension of the process of differentiation also to clinical medicine. I am of the opinion that clinical medicine as it exists now is made up of two constituents: one part has all the elements of a pure science and ought to be coordinate to the other pure sciences of medicine, and the other part is the real practice of medicine, an applied science which has many elements of an art. At present both parts are so closely interwoven that they present the appearance of a natural unit the splitting of which into two parts might appear to some as an impossible and undesirable process."

* * * *

"To clinical medicine is left the study of the phenomena and their sequence as they occur in a living body during the entire course of a disease. It has to interpret these phenomena by known physiologic laws, to identify them with similar phenomena experimentally produced in animals and it has to correlate the phenomena observed in the course of a certain disease during life with the anatomic changes found at the postmortem examinations in case the disease has a fatal termination. It is also one of the tasks of clinical medicine to study the influence on the onset and course of phenomena of diseases which certain means and remedies may exert whose physiologic actions are well established. In other words, the domain of clinical research comprises the study of the natural history of diseases, their physiology and their pharmacology. Can there be any doubt that these studies constitute legitimate objects of a pure science?"

* * * *

"After showing that there is a definite field for a science of clinical medicine the next question is who should be the men to carry on the research in this field? What should be their qualifications? In the first place, they must have a training fitting them to carry out investigations in conformity with the requirements existing in all pure sciences. They must not only be informed and trained in the other sciences of medicine, but must have carried on various investigations in one or more of these pure sciences, so as to become familiar with careful scientific methods and imbued with a scientific spirit. They will thus learn best how to shape a problem so as to make it amenable to a solution; how to marshal the consecutive steps of an investigation so

as to bring out the reply to the question in hand. They will learn to avoid bias in the search, to apply criticism to the findings; they will learn not to trust only few facts, not to rejoice prematurely over findings and not to be disheartened by failures. They will thus acquire the habits and the tastes of the investigator, the scientist, which may then stick to them for life.

"However, after all these preparations they must select clinical research as the main field of their scientific activity. Clinical science will not thrive through chance investigations by friendly neighbors from the adjoining practical and scientific domains. Such volunteer service which for the present is keeping up the cultivation of the unclaimed region is most certainly very welcome. But the acclamation, cultivation and maintenance of a field of pure science of clinical medicine cannot be accomplished by chance services from volunteers; for such a purpose we need the service of a standing army of regulars. The investigator in clinical science must devote the best part of his time and intellectual energies to the cultivation and elevation of this field just as the physiologist does in his domain—or at least as he ought to do."

* * * *

"Let me recapitulate. There is a necessity for a differentiation of clinical medicine into a science and a practice. The clinical science has well-defined objects and is a most important department. It must be managed by a set of men specially trained for and almost exclusively devoted to that task. Without the development of such a department of clinical science the efficiency of the practice of internal medicine will lag behind, no matter how progressive the allied sciences of medicine are and how great their efforts to be useful to medicine may be.

THE CONDITIONS AS THEY ACTUALLY EXIST

"In conjunction with the foregoing considerations let me glance at the conditions of clinical medicine as they actually exist here and abroad. I may state that neither abroad nor here do we find a separate class of investigators confining their activity solely to the domain of the science of clinical medicine. Everywhere science and practice of clinical medicine go hand in hand. We may, however, admit at the outset that there is an enormous difference in the status of medical research between abroad and here. Let us take the development and the present status of clinical medicine of the German-speaking countries as an illustration of the conditions abroad. We shall notice that there the mother-stem of medicine managed to retain a scientific aspect despite all processes of differentiation."

* * * *

"Teaching medicine and furthering its science is a very serious business which ought to be carried on by men who are ready to devote all or most of their time to it.

"Here are problems for you to solve. The progress of clinical medicine in this country has to be accelerated again. We might reach the level which we have seen

to exist abroad. But we ought to strive to get still higher; in this field lack of modesty is a stimulating virtue. Look at the allied sciences of medicine, the level which they have reached in a comparatively short time without any tradition and only through the activity of a small group of high-minded men. The progress of medicine in this country was always carried on by the few and not by the masses. Clinical medicine must reclaim some of the brainy young men who were enticed by the sciences of medicine. You represent a new generation. You have had an education and a training in modern medicine and the allied sciences. You have a training in investigation, the constitution requires it of you. The constitution which you have adopted shows your spirit. Among its objects is 'the cultivation of clinical research by the methods of the natural sciences and the diffusion of a scientific spirit among its members.' But you will accomplish more; the constitution imposes on you the obligation to be active in the diffusion of the principles of the Society particularly among the students who come under your charge. I would recall this obligation to the minds of the members who were called within this year to chairs of medicine at influential places. The constitution does not keep you down exclusively to science, but let me tell you: beware of practice. It is a bewitching graveyard in which many a brain has been buried alive with no other compensation than a gilded tombstone."

The growth of the Society was rapid. In 1914 there were more than 70 members. Of these, 41 were at the meeting and 25 papers were read.

Steps had to be taken at that meeting to limit future programs to permit completion of the program in a single day.

Ever since there have been discussions as to the relative merit of a one-day meeting with a single program, a one-day meeting with simultaneous sessions in different fields of interest, and a two-day meeting. The second alternative has been used in a few meetings; but the first has been the usually favored procedure.

In 1924, to provide for the ever increasing group of young workers in the field of clinical investigation, the constitution was amended to limit active members to 200 and to transfer to emeritus status all whose membership had extended through 20 years, and to permit voluntary transfer to emeritus status after ten years of active membership.

This interesting step, so far as I know unique among our national scientific societies, has insured the persistence of an atmosphere of youthful vigor in this organization. This step was rendered easier by the custom, dating uninterruptedly from the first meeting, of holding the meetings of this society on the day preceding the meeting of the

Association of American Physicians and at the same place.

The Journal of Clinical Investigation

The Constitution of the Society provided for publication of abstracts of its papers.

Early there arose a desire to support an organ of publication which might set a high standard in the field of clinical investigation and encourage its growth.

Realization of this hope became possible when in 1923 the Rockefeller Institute offered to subsidize through its early years a journal to be owned and operated by the Society. Dr. G. Canby Robinson was selected as Editor. Six members of the Society were elected as the first Editorial Board. The formulation of general policies and the election of Editor and Editorial Board was made the responsibility of an Editorial Committee of 15 members each to serve three years; five of its members retiring each year, with the vacancies filled by elections by the Society at its annual meeting.

The first issue of *The Journal of Clinical Investigation* appeared in October, 1924, and subsequent numbers appeared at bimonthly intervals. Early volumes vary in the period of a year covered, for those volumes were closed whenever a prescribed quota of pages had been issued. Later the *Journal's* volume became identical with the issues of a calendar year.

When the subsidy from the Rockefeller Institute ceased, financial aid was given for several years by the Rockefeller Foundation. For the next few years many of the departments of medicine of our universities accepted associate memberships in the Society as a form of subsidy for the *Journal*.

With Volume XI in 1932 the Chemical Foundation became interested in the project through the efforts of Dr. G. Canby Robinson. It began meeting all deficits in the costs of the *Journal* and continued this until recently the growth of the subscription list has placed the *Journal* on a self-supporting basis. During the recent war the Commonwealth Fund has aided the *Journal* by a grant to facilitate publication of studies arising out of the problems of the war.

The editorial staff for the first few years of the *Journal* is not recorded in the bound files of the *Journal*, for this information appeared only on the

cover pages of those issues and these pages are discarded on binding. The following tabulation has, therefore, some reason for record.

EDITORS

G. C. Robinson	<i>Editor</i>	1924-1927

The most complete library collection of these early Proceedings is, according to the latest Union Serials List, the New York Academy of Medicine Library, which at present has the reprints for the following meetings: 1, 2, 3, 4, 6, 7, 8, 11, 12, 13, 14, 15, 16. In the same library are Lists of Members 1909, 1910, 1916 and Triennial Catalogues 1923, 1926, 1932.

So in brief is the story of the founding of our Society, of its goals and accepted functions, of its constitution gradually modified to meet the needs

of the organization, and of the institution and growth of *The Journal of Clinical Investigation* which the enthusiasm of this young Society and the generosity of sympathetic foundations have made a realized possibility.

No one can compare the first presidential address with the record of the Society's achievements and not recognize the outstanding success with which our Society has served the purposes for which it was founded.

LETTER FROM THE EDITORS

CLINICAL INVESTIGATION

The Editors are frequently confronted with the question as to what is and what is not clinical investigation. It is true that the physician who continues to develop his clinical acuity and maturity of judgment by constant observation of the patient is employing the most ancient and still a most valuable technique of clinical investigation. A natural outgrowth of the descriptive stage of medical knowledge occurred when clinical investigation became related to morphology, with anatomy and pathology providing the foreground and background between which the patient, as an example of altered structure and function, found a somewhat uncomfortable place. With rapid advances in chemistry and physics the role of disordered function was explored by those whose main contribution was providing physical juxtaposition of patient and experimental laboratory. The paraphernalia of the laboratory with rapid multiplication of apparatus and test led to the notion that the more numerous the exact facts the better was the understanding of disease. This is true. It was forgotten, however, that abstract disease, without focus in a sick person, has no meaning.

For a time clinical investigation was carried along in the expanding domain of the laboratory and to a degree was synonymous with chemical investigation. A new test was devised and there appeared in medical journals an outpouring of reports on its application to a great miscellany of conditions. Blood levels and contents, clearance tests, tolerance tests, pH, and milliequivalent became the *sine qua non*. While this extension of the physical examination into the laboratory yielded a rich harvest, a tendency arose for the laboratory datum to displace other aspects of the patient from the student's attention. There were indications that study of the part might obscure the whole. The use of instruments sometimes became an object in itself and there arose the cult of the sphygmomanometer, the electrocardiogram, the electroencephalogram, the metabolism machine, and others, each eminently useful as a stepping stone to fuller knowledge of a sick person but reaching an early state of diminished returns as minutiae were explored.

This is not to decry the advances in knowledge as such, but the fact that the clinical investigator was so often led away from the patient because of his preoccupation with a test or an implement. This state of affairs comprises specialization and has brought benefits no one would willingly discard. The danger is that in concentrating on one aspect of disease so intensively the student risks a gain in knowledge at the sacrifice of wisdom. And the wisdom which clinical investigation should supply is to look at the sick person not as the inevitable but uninteresting vehicle of a fascinating lesion or syndrome but *whole*—related to external as well as internal environment. New trends in this direction are found on many sides and the recent emphasis on emotional, social and economic factors in human sickness is a healthy sign of a return to the patient as a person.

Psychosomatic medicine, a cumbersome though useful term, epitomizes this tendency. Clinical investigation must now include this broader approach in order to obtain and correlate facts from the environment as they relate to a patient and his disease. It should be remembered, however, that investigation into such problems not only is most difficult but requires maturity and a sound working knowledge of the phenomena of health and illness. Unless the method of comparison and control which has been developed in the traditional form of clinical investigation is applied in this newer area the fragmentation inherent in a new specialty may disintegrate rather than integrate our approach to disease.

Essentially, clinical investigation is the study of the sick person, his past experiences and adaptations, and their relation to his present plight as it is manifest by deviations in structure, function and behavior, and the internal and external processes upon which they depend. Orientation exclusively to either the internal or the external events of disease, or to only portions of these two major fields for clinical investigation must lead inevitably to the dissipation of our efforts to gain that true understanding upon which must be based present treatment and future prevention of the disorders which vex both the patient and his physician.

SOME OBSERVATIONS ON THE DEVELOPMENT OF HYPOKALIEMIA DURING THERAPY OF DIABETIC ACIDOSIS IN JUVENILE AND YOUNG ADULT SUBJECTS

By L. GREENMAN, F. M. MATEER, R. C. GOW, J. H. PETERS, AND T. S. DANOWSKI

(From the Department of Research Medicine, the Children's and Presbyterian Hospitals, and the Rensselaer Foundation, University of Pittsburgh School of Medicine, Pittsburgh)

(Received for publication October 18, 1948)

It is known that hypopotassemia may appear during therapy of diabetic acidosis or coma, at times associated with muscular paralysis (1-9). This is not, however, an invariable occurrence, nor have the origins of such decreases in the serum and interstitial fluid potassium concentrations been clearly defined. It seems probable that one or more mechanisms are responsible. These include the possibilities that hypokaliemia¹ develops as a result of a continued loss of potassium in urine, that it is a manifestation of dilution of body fluids by potassium-free solutions administered during therapy, and, finally, that it results from movements of potassium into body cells. The studies herein reported evaluate the role of each of these factors in a limited number of patients, chiefly pre-adult, in whom intensive study using the balance method was possible.

MATERIALS AND METHODS

Nine patients have been studied during a total of 11 admissions for the treatment of diabetic acidosis. Two of the subjects were young adults; the remainder were children seven to 16 years of age. Over-breathing was definitely present in each case; the serum carbon dioxide content ranged from 2.6 to 10.4 m.eq. per liter on admission. All patients were conscious, though difficult to arouse. Definite vascular collapse was present in only one patient, R. J., requiring three transfusions. Anuria did not develop in any of the subjects. Insulin was administered subcutaneously to all patients, although J. K. and T. W. also received large intravenous injections initially. Data on the retention of potassium salts administered in large amounts during convalescence to eight of the cases have been presented in a previous communication (9). The studies herein reported are based on observations from the time of admission and continued until convalescence was well established. During these inter-

vals the patients received insulin, glucose, saline, and *only little, if any, potassium.*

The experimental procedure employed and the methods of calculation have been previously described in detail (9-12). Briefly they may be summarized as follows: the chloride space, corrected for the external balance of this ion and for changes in the chloride concentration in serum, has been used as an index of alterations in the volume of extracellular fluid. The intake and the urinary excretion of sodium, potassium, chloride, glucose, and nitrogen were measured during intervals marked at the start and finish by determinations of the values of these various components in serum. The retention or loss of these cations and of nitrogen has been apportioned between the extracellular fluid and the cells. In the case of nitrogen, suitable corrections for changes in the concentration of the whole blood nonprotein nitrogen were made. The values for the cell balances of potassium represent, therefore, changes in excess of those which might be expected with the anabolism or catabolism of cell protein, employing the usual ratio of 1 gram nitrogen: 2.38 m.eq. of potassium.

It must be emphasized that the experimental procedure and the methods of calculation employed yield only the *over-all balance* of any particular component studied. Thus it should be clear that if the over-all loss of potassium from cells during any individual period should prove to be 40 m.eq., the possibility cannot be excluded, for example, that muscle cells actually lost 70 m.eq. but that this was reduced to 40 m.eq. by a movement of 30 m.eq. into the liver with glycogen.

RESULTS

From Table I it is evident that during treatment the serum potassium declined progressively to abnormally low levels in seven of the 11 cases. In two instances in which this did not occur, patients L. B. and M. S., hypopotassemia was already present on admission. In the former the potassium level remained low, while in the latter a rise was observed. In the two other patients, J. K. (a) and W. S., potassium decreased during treatment, but remained within normal limits.²

² All patients, save R. J., had received insulin, protamine or regular, within the 24 hours preceding admission.

¹ This term has been taken to refer solely to diminished concentrations of potassium in blood serum or plasma and the contiguous interstitial fluid, and does not necessarily indicate any decrease in the total amount of potassium in these fluids.

* Average value of the other cases used in calculating concentrations in extracellular water.

† NPN of 60 on admission assumed for calculation of cell N balances.

‡ Represents weight obtained by calculation, using subsequent weight corrected for intake and losses of water and solids.

Throughout these early hours of therapy each patient continued to excrete urine which contained measurable amounts of potassium (Table II). In no instance did the urinary excretion of this ion

decline to zero. These findings are in keeping with those of Atchley *et al.*, whose subjects also continued to excrete potassium during the period of treatment (13). The magnitude of this loss

in the study cited was less than in the pretreatment period, but in no instance was it entirely cancelled.

Furthermore, comparison of the external and the extracellular balances of potassium, as tabulated in Table III, indicates clearly that, with but one significant exception, the cells were losing potassium as serum levels declined. Only one patient, T. W., had received enough potassium in the intake to produce a positive balance of cell potassium. It is to be noted that these negative balances of cell potassium cannot be attributed

solely to the breakdown of protein. This is apparent from the net balances of cell N corrected for changes in the NPN, as recorded in the final section of Table III. Using the 2.38:1 cell K:N ratio it may be seen that in no instance was the negative cell N balance of sufficient magnitude to account for the entire loss of cell potassium. Neither were the negative balances of cell potassium cancelled when cell N balances became positive. *It would appear therefore from the above data that, based on the methods of calculation described earlier, potassium continued to pour out*

* Balance data are expressed per individual period rather than cumulatively, and are corrected for the electrolytes and N withdrawn in serum samples.
† Changes in NPN have been taken into account in calculating the balance of cell N; the K balances represent changes in excess of the transfers associated with the anabolism or catabolism of protein.
‡ 6.5 to 23.0 hour urine specimen lost and hence calculation of balances for this period is not possible.

of cells throughout these earlier hours of therapy. It is germane to the argument of this paper to declare at this point that these continued negative balances of cell potassium, even when corrections for protein metabolism have been made, represent an observed fact. Their validity cannot be denied, but rather must be reconciled with the finding that, during these same periods of study, utilization of carbohydrate or its deposition as glycogen was taking place. This interpretation is supported by the finding that the blood sugar concentrations fell progressively while carbohydrate was administered (Table I). The balance data, Tables II and III, further indicate that administered carbohydrate was, in fact, catabolized or stored.

During these same intervals of treatment the patients received parenteral fluids in the amounts indicated in Table II. In the majority of these periods, actually 16 out of 24, this resulted in a measurable increase in the extracellular volume. These changes, based upon the balance of chloride corrected for alterations in the concentration of the chloride ion in extracellular fluid, are readily identifiable in the second section of Table III as instances in which the extracellular balance of water had risen by 0.5 liter or more. This value has been taken as a reasonable approximation of a change which definitely falls outside the range of the errors inherent in these methods of analyses and calculations (10, 11, 14). It is to be noted that in the remaining eight of the 24 periods the

extracellular space either failed to change significantly, or actually declined in volume. *These findings clearly suggest that in many, but not all, of our patients the extracellular fluid was diluted by the administration of potassium-free solutions.*

DISCUSSION

The data presented have established the following facts: (1) patients undergoing therapy for diabetic acidosis continue to excrete measurable amounts of potassium in the urine, (2) during this interval, if no potassium is administered, the over-all balance of cell potassium remains consistently negative, even though potassium is at times deposited with protein and the carbohydrate balances become positive, and (3) fluid therapy with potassium-free solutions during this time frequently results in an expansion of the extracellular volume.

In view of the above statements it is reasonable to suggest that in any particular patient recovering from diabetic acidosis, continued urinary loss of potassium, as long as potassium-containing urine is elaborated, will be a contributory factor in the development of hypopotassemia. Similarly, re-expansion of the body fluids, particularly of the extracellular volume, by means of solutions devoid of potassium will also tend to produce low serum and interstitial fluid concentrations of potassium. Finally, the deposition of potassium with glycogen or with protein will remove potassium from the extracellular fluid, and thereby cause hypokaliemia (10, 15). Obviously, the importance of any one of these processes in the origin of hypokaliemia will vary with its magnitude and direction. Analyses of our own group of cases, based on estimation of the total amount of potassium in the extracellular compartment at the start and at the end of an interval during which the potassium concentration had dropped, indicate that the dilution of body fluid with potassium-free fluid is at times sufficiently large to account for the entire decrease in serum potassium concentration. Less often the drop appears to be explicable by a combination of dilution of body fluids and continued urinary losses of potassium. Only rarely can the low levels be explained solely by urinary losses of the cation (Table III).

In no instance, irrespective of the roles played by dilution or by renal excretion in the production of hypokaliemia, is the movement of potassium into cells precluded. This is true even though the net balances of cell potassium are negative. As already indicated, nitrogen was deposited with potassium in the cells in a number of the periods. Similarly, glycogen must have been deposited with potassium in the liver during the recovery phase (15). This is apparent from the *in vivo* studies of others and is supported by the positive carbohydrate balances in our own series (16). It is clear that though these processes undoubtedly occurred, they were usually not, in our series of cases, of sufficient magnitude to cancel entirely the tendency for cells to lose potassium during the early treatment and recovery phases of diabetic acidosis. The explanation for this negative net balance of cell potassium is not available. It may well be merely a continuation, at a reduced pace, of mechanisms which result in cell potassium loss during acidosis.

SUMMARY AND CONCLUSION

A small series of juvenile and young adult diabetics undergoing therapy for acidosis has been studied by means of the balance method. It appears that during this early phase of therapy dilution of body fluids by potassium-free solutions, continued urinary loss of potassium, and migration of potassium out of the extracellular phase into cells with the deposition of protein or of glycogen, even though the over-all balances of cell potassium remain negative, may each contribute to the hypokaliemia which develops.

THE EFFECT OF BILATERAL STELLATE GANGLION BLOCK ON THE CEREBRAL CIRCULATION IN NORMOTENSIVE AND HYPERTENSIVE PATIENTS¹

By M. H. HARMEL,^{2,3} J. H. HAFKENSCHIEL, G. M. AUSTIN,
C. W. CRUMPTON,⁴ AND S. S. KETY

(From the Departments of Pharmacology and Anesthesiology, the Edward B. Robinette Foundation, Medical Clinic, Hospital of the University of Pennsylvania, and the Harrison Department of Surgical Research, University of Pennsylvania School of Medicine)

(Received for publication December 12, 1948)

Stellate ganglion block has been used in the treatment of cerebral derangements thought to be associated with angiospasm, for the purpose of relieving spasm and presumably increasing the cerebral blood flow (1-4). In view of this clinical development the question of the role of the sympathetic nervous system in the control of the cerebral circulation becomes more than an academic one. The only experimental work in man has been that of Risteen and Volpitta (3) who observed through burr holes an increase in the diameter of the pial vessels following stellate block. A number of clinical observations, ascribing dramatic results of stellate block to the release of cerebral angiospasm, have appeared since Leriche and Fontaine (1) first reported their experience with two cases of cerebral embolism. With the development of the nitrous oxide method for measuring cerebral blood flow (5-7) a quantitative technique has been made available for clinical study of this problem. Quantitative data can be obtained concerning the fundamental physiology of the cerebral circulation following block of that part of the sympathetic innervation of the cerebral vessels passing through the stellate and middle cervical ganglia. This information may permit evaluation of stellate block as a means of

therapy in cerebro-vascular derangements. The following studies were undertaken in an effort to explore these problems.

METHODS

Thirteen patients were studied; their diagnoses are given in Table I. In all patients except A.S. and J. C. there was a therapeutic or diagnostic indication for performing stellate block. With the exception of R. H., all patients were ambulatory and in full possession of their faculties. R. H. had been injured three weeks prior to the study and was aphasic and disoriented at the time of study. The patients with Parkinsonism were studied as outpatients. All the hypertensive patients came from the medical wards.

Mean arterial blood pressure (MABP) was measured from the femoral artery by a damped mercury manometer attached directly to a needle in the artery. Blood oxygen and carbon dioxide analyses were carried out by the manometric technique of Van Slyke and Neill (8). Blood pH measurements were made anaerobically at 37° C. using a glass electrode. Carbon dioxide tensions ($p\text{CO}_2$) were calculated according to the nomograms in Peters and Van Slyke (8). Cerebral blood flow (CBF) was determined by the nitrous oxide method using 21% oxygen, 64% nitrogen and 15% nitrous oxide as the inspired gas mixture (6, 7). From this value and the mean arterial blood pressure the cerebral vascular resistance was calculated (6).

The patients received no medication prior to the study. Following a control cerebral blood flow measurement bilateral block of the stellate ganglia was performed using the technique described by Pereira (9). Either 1% procaine or 1% intracaine without adrenalin was used, 20 cc. of solution being injected on either side. The criteria for an effective block were: scleral and conjunctival injection, ptosis, narrowing of the palpebral fissure, miosis and anhidrosis of the forehead. The block was usually evident within five minutes, reached its height within 15 minutes and lasted from 45 to 60 minutes. When block of the second side was judged to be complete, a second cerebral blood flow measurement was performed.

RESULTS

The data are presented in Tables I and II. It will be seen that the patients comprise a clinically heterogeneous group. In the series as a whole neither the cerebral blood flow nor the cerebral vascular resistance was significantly changed following the stellate ganglion block. However, when the hypertensive group is considered separately, there is a significant increase in cerebral vascular resistance (3.3 to 3.8, $p < 0.05$) with no significant change in the other functions studied. The predominance of hypertensive persons explains the high mean arterial blood pressures recorded. The cerebral vascular resistance is considerably elevated for the hypertensive patients in this group as previously described (10). We feel that the cerebral vascular resistance most explicitly conveys information concerning the tonic state of the cerebral vessels. It seems unlikely that changes in intracranial pressure or blood viscosity of a magnitude sufficient to affect cerebral vascular resistance occurred during these experiments (11).

DISCUSSION

Our observation that bilateral stellate ganglion block in our patients produced no measurable change in the cerebral circulation is in contrast with the presumption that this procedure leads to dilatation of the cerebral vessels and an increase in cerebral blood flow (1-4). It does not, however, prove that the cerebral blood vessels of man are without sympathetic control, nor rule out the possibility that under abnormal conditions there may be vasospasm of sympathetic origin. To prove the former, one must be certain of having excluded all sympathetic nerve impulses to the brain. This cannot be assured even for those impulses which pass through the stellate ganglia, for the local block may have been incomplete. Complete surgical extirpation of the stellate ganglia would undoubtedly be the best approach in studying the physiology of the intrinsic nervous control of the cerebral circulation (12). Local block, though admittedly less certain of interrupting the sympathetic pathways, is the technique used currently in clinical therapy. Furthermore it is by no means certain that all the sympathetic fibers to the brain pass through the stellate gan-

glia (13, 14). As for the possibility that the situation may be different under other clinical conditions, such as acute angiospasm, only further study can give an adequate answer. None of the subjects of these experiments showed any symptoms suggesting acute cerebral angiospasm.

An apparent increase in the cerebral vascular resistance of the hypertensive patients calls for comment. We feel that this was probably the result of a relatively greater flow through the facial veins causing a greater extracerebral contamination in the presence of an unchanged cerebral blood flow. On the basis of this hypothesis one would expect an increased cerebral vascular resistance, a decreased cerebral blood flow (50 to 45) and a decreased cerebral oxygen uptake (3.5 to 3.0). Although these latter changes are not statistically significant they are in a direction compatible with the thesis. That this should occur in the hypertensive group and not in the other patients may be explained by the higher mean perfusing pressure during the block in these patients. These findings indicate that the usually small error in the nitrous oxide method due to contamination (6) may be magnified when blood flow through the skin is significantly increased.

We conclude that quantitative measurements of the cerebral blood flow in man gives no indication that bilateral stellate block causes an increase in cerebral blood flow or diminution in the tone of cerebral vessels. These results are compatible with the thesis that the sympathetic nervous system plays little role in the intrinsic control of the cerebral circulation under the conditions studied (including essential hypertension). An evaluation of the mechanism of improvement following stellate block as a therapeutic measure in man cannot be made until studies have been made in patients presumed to have acute cerebral angiospasm.

SUMMARY

1. In 13 patients quantitative studies of the cerebral blood flow and cerebral vascular resistance were made using the nitrous oxide technique before and after bilateral block of the stellate ganglia.
2. There were no significant changes in any of the functions studied before and after block.

PEPTIDASE ACTIVITY IN HUMAN SERUM FOLLOWING BONE FRACTURE

By KARL STERN, ANDREA M. CULLEN, AND VIRGINIA T. BARBER

(From the Gerontological Unit, Department of Psychiatry, McGill University, Allan Memorial Institute, Montreal, Canada)

(Received for publication November 29, 1948)

In a previous communication (Barber *et al.* [1]) it has been shown that there exists in human serum a cobalt-activatable enzyme which splits L-leucylglycylglycine (LGG). The rate of hydrolysis in normal adult individuals is between 5.5 and 8.5% per hour (in the previous communication the rate of hydrolysis of LGG by serum of normal adult controls was stated to be 6.1 to 7.8% per hour. This value had to be revised on the basis of more subjects investigated since then).

This investigation was originally planned for the clinical study of tissue reactions of the ageing organism. The present communication is not immediately related to this problem but seems to have considerable pathophysiological significance: following fractures there was found to be an abnormal rise in the activity of the LGG-splitting enzyme in human serum.

Ever since the studies by Cuthbertson (2) and Browne (3) and their co-workers, numerous clinical and experimental investigations have been made on the metabolic aspects of injury and repair. There have been many attempts to explain these observations on the basis of one hypothesis but so far no single mechanism has been discovered which could account for the irregularities of protein metabolism accompanying injury and repair. Therefore, every new observation is significant in spite of the fact that its functional meaning may not be clear on the basis of our present-day concepts.

METHODS AND MATERIAL

Blood was obtained by venous puncture from nine patients who had suffered fractures of varying degree. Serum was prepared immediately by centrifugation and stored for not more than 24 hours in a refrigerator. The tri-peptide L-leucylglycylglycine was used as substrate for the determinations which were carried out in triplicate in 2.0 cc. volumetric flasks. The reaction mixture, made up of 0.2 cc. serum per cc., 0.001 M cobalt sulphate, 0.05 M LGG, was kept near pH 7.8 with 0.01 M phosphate buffer

and made up to volume with redistilled CO₂-free water. To each tube, 0.01 ml. toluene was added as preservative. Flasks containing serum and substrate controls were prepared, and a zero-time titration was carried out on 0.2 ml. aliquots of the test solutions, according to the micro-technique of Grassmann and Heyde (4). The preparations were then incubated in a water-bath at 39° for six hours, during which time three titration readings were taken. Corrections were made for the controls and the results plotted on a graph. The rate of hydrolysis was calculated from the slope of the zero-order plot of per cent hydrolysis versus time (Barber *et al.* [1]).

In one case (OT), in addition to the peptidase activity, the white blood count, differential, and sedimentation rate were investigated.

RESULTS

The results are demonstrated in Tables I and II and in Figure 1. We see that out of nine cases of fracture the value of hydrolysis was abnormally high in eight.

TABLE I
Serum peptidase activity following fracture

Name	Sex	Age	Nature of injury	Time after injury	Hydrolysis of LGG % per hr
BE	M	40	Crushing injury to left hand Loss of tip of index finger	1 day 7 days	15 10.4
BR	M	58	Compound fracture of left fibula	4 days	13
DI	M	62	Right leg fracture	1 day	12.6
KL	F	48	Fracture lower end of radius	3 hours	6.7
LE	F	29	Fractured pelvis	1 day	14
WE	F	35	Lumbar fracture Fractured arm	10 hours 6 days	14.6 8.4

The one exception was a case of fracture of the lower end of the radius. It is noteworthy that in this case the blood was obtained sooner after the injury (three hours) than in any other. In another case (lumbar and arm fracture combined) the time interval between injury and blood examination was 10 hours; in this case the rate was 14.6% which belongs to the highest range

dase activity has practically reached the normal value.

DISCUSSION

We see that in eight out of nine cases of fracture the activity of the LGG peptidase of the serum was significantly increased. The one exception was a case of a relatively minor fracture in which the blood was taken sooner after the accident than in any of the remaining cases. On the other hand, the patient whose peptidase activity was highest (20% on the 32nd day) had suffered the most widespread and severe injuries. This would, at first glance, suggest a correlation between severity of injury and degree of peptidase activity; however, the number of cases is too limited to allow such a conclusion.

What is the possible mechanism of this phenomenon? Fruton (6) discussed the widespread distribution of peptidases capable of splitting LGG, in intestinal mucosa, in lymph and muscle, and in leucocytes and lymphocytes, suggesting that they may have a common origin in the leucocytes and lymphocytes invading the tissue. Holman, White and Fruton (7) observed an increase in the manganese-activatable LGG serum peptidase activity following the injection of adrenocorticotrophic hormone into mice and rabbits, and considered this to be associated with the resultant turnover of lymphoid tissue. If this is so, then our observed increases in peptidase activity during the healing of fractures might be directly correlated with the leucocytic reaction at the site of the fracture. Moritz (8) states that the reactive inflammation with exudation begins "soon after the injury has been sustained and reaches its maximum between ten days and two weeks." From experiments carried out in our laboratory, the injection of adrenocorticotrophic hormone into normal control subjects is not followed by any striking increase in the activity of the cobalt-activatable serum peptidase.¹ Moreover, in cases of acute infections there was no parallel between the numbers of circulating lymphocytes and the activity of this enzyme.

The changes in protein metabolism associated with injury and repair have been discovered comparatively late (Cuthbertson [9]). Since then a wealth of observations has been produced. From

the careful review by Beattie (10) it is quite obvious that there is no one theory on which the various metabolic phenomena associated with injury and repair could be explained. In only one of our cases (Figure 1, Case OT) was it possible to observe the nitrogen balance² together with the peptidase activity; in this case the peptidase activity began to decline with the onset of a positive nitrogen balance. Ingle *et al.* (11) demonstrated that adrenalectomized rats did not show the characteristic negative phase of the N-balance following fracture. From this it would seem that the presence of an adrenal hormone is essential for this reaction. However, as noted above, in normal human subjects we failed to obtain any striking increase in serum peptidase activity following injection of adrenocorticotrophic hormone. Thus we see that fractures are associated with a rise and return to normal of the peptidase activity of the serum during the course of healing. However, on the basis of present-day knowledge we have no definite theoretical explanation of this phenomenon. Observations like these may well lead to a procedure which would be clinically useful in the evaluation of wound healing.

SUMMARY

Eight out of nine cases of fracture showed in their blood serum an increase in the activity of the cobalt-activatable enzyme which hydrolyses LGG. In three cases studied longitudinally the rate of hydrolysis returned to normal during the course of healing. In one of these cases nitrogen balance studies were done simultaneously. In this case the activity of the enzyme began to decline when a positive nitrogen balance was established.

THE RENAL REGULATION OF ACID-BASE BALANCE IN MAN. IV. THE NATURE OF THE RENAL COMPENSATIONS IN AMMONIUM CHLORIDE ACIDOSIS¹

BY O. W. SARTORIUS, J. C. ROEMMELT, AND R. F. PITTS WITH THE TECHNICAL
ASSISTANCE OF DOROTHY CALHOON AND PHYLLIS MINER

(From the Department of Physiology, Syracuse University College of Medicine,
Syracuse, New York)

(Received for publication December 6, 1948)

The major body buffers, including bicarbonate, plasma and tissue proteins and intracellular organic phosphate complexes, can yield sufficient base within a pH range compatible with life to neutralize at most 1 mol of strong acid (1). As an immediate compensation for the invasion of the body by acid, urine of increased hydrogen ion concentration is formed, but since the pH of the urine is limited to a minimum of 4.4 to 4.7 (2, 3), the quantity of strong acid which can be excreted in free form is negligible. Acid is at first eliminated fully neutralized by base derived from the above mentioned buffers (4-6). According to Gamble the resulting depletion of base stores serves to stimulate the production and excretion of ammonia. Over a period of several days ammonia is substituted in progressively increasing amounts for fixed base in the urine, until eventually nearly all of the acid is eliminated in combination with ammonia (4-7). During recovery from acidosis the excretion of ammonia remains high, and base derived from ingested salt is retained in the body to rebuild buffer stores. Only after these stores are replenished does the excretion of ammonia decrease to normal levels.

The loss of base from both intra- and extracellular compartments during the initial phase of acidosis is accompanied by a compensatory loss of water, leading to cellular and interstitial dehydration and to reduction in circulating plasma volume (4, 6). Presumably this latter factor is responsible for the reduction in urea clearance and for the nitrogen retention often observed in severe acidosis (8). However, loss of fluid does not completely compensate for loss of alkali, for the total

base concentration of the plasma usually decreases significantly (4, 6, 9-11).

The acidosis of diabetic ketosis differs from that outlined above chiefly in the greater contribution of titratable acid excretion to total acid elimination (1, 12, 13). Because of the weakly acidic nature of beta-hydroxybutyric acid appreciable quantities of acid can be eliminated in free form in urine of maximal acidity. In severe diabetic ketosis as much as 0.15 mol of titratable acid may be excreted per day. However, providing the development of ketosis is slow, some two to three times this quantity of acid is eliminated in combination with ammonia. In rapidly developing ketosis, loss of base and dehydration may reach lethal proportions before the renal production of ammonia increases sufficiently to balance the acid load (14, 15). In chronic nephritis the renal capacity to excrete ammonia is reduced (16, 17), and since acid is eliminated for the most part in combination with fixed base, the buffer reserves of alkali suffer progressive depletion (9, 18, 19).

The present study of the response of the normal kidney to an increased load of strong acid was undertaken (a) to relate the rates of excretion of the several ions to their respective plasma concentrations, (b) to determine the nature and extent of the changes in glomerular filtration, renal plasma flow, and ionic reabsorption which underlie altered excretory functions in metabolic acidosis, and (c) to study the time relations of the renal compensations to acidosis. A number of complete though separate studies of acid-base equilibria of plasma and of urinary electrolyte balance have been made in experimental acidosis and in the acidosis of chronic nephritis and diabetes (9, 10, 12, 13, 16-18). However, in no study to date have electrolyte balances been re-

¹ Aided by grants from the United States Public Health Service and the John and Mary R. Markle Foundation.

lated to the changes in plasma composition and renal function which ultimately determine their character. The data presented below partially fill this void.

METHODS

Three types of experimental procedures were applied in this study.

(a) Two healthy adult males were maintained for periods of 15 and 16 days respectively, on a diet constant with respect to salt content and caloric value. Accurate 24-hour urine samples, preserved with toluene, were collected during these periods. Daily blood samples were drawn from a superficial vein after soaking the forearm in water at 47° C for 10 min. to render the composition of the venous blood essentially that of arterial blood. The plasma and urine samples of both subjects were analyzed for sodium, chloride, bicarbonate, pH, and phosphate. Hematocrit, urinary specific gravity and urinary content of titratable acid and ammonia were determined daily. The plasma and urine samples of the second subject were in addition analyzed for potassium, calcium, sulphate, and protein, while the urine was further tested for magnesium, organic acid, creatinine, creatine, and amino nitrogen. In

the first experiment sodium was analyzed by the method of Butler and Tuthill (20). In the second experiment, sodium and potassium were determined by an internal standard flame photometer² with an accuracy within ± 2 per cent, as checked against the method of Butler and Tuthill. Magnesium was precipitated as the ammonium phosphate and the latter ion determined colorimetrically (1). Plasma proteins and specific gravity were determined by the copper sulphate method of Phillips *et al.* (21). Organic acid in urine was determined by electrometric titration of aliquots between limits of pH 8.0 and 2.7 following removal of phosphate with calcium hydroxide. Titrations were corrected for creatinine content of the urine (1). Other methods employed have been described in previous communications (3, 22). The first five days of each experiment constituted the control period; the second five days, the period of acidosis; and the remaining five or six days, the recovery period. The first subject ingested 15 gms. of ammonium chloride daily in divided doses for the initial two days of acidosis followed by 10 gms. daily for the

² We are indebted to Dr. Robert L. Bowman of the Department of Medicine of New York University College of Medicine for the design of our flame photometer and for his helpful advice during its construction.

remaining three days. The second subject ingested 15 gms. daily throughout the period of acidosis.

(b) Renal clearance experiments were performed at intervals during the control, acidosis, and recovery periods. In the first subject, the rate of glomerular filtration was approximated by mannitol clearances,³ performed on the first and fourth days of the control period, the second and fifth days of acidosis and the fifth day of recovery. In the second subject, inulin was used as an exact measure of glomerular filtration rate. Determinations were made on the first and fourth days of each of

³ According to recent studies of Berger *et al.* (23) the mannitol clearance is significantly lower than the inulin clearance, hence is not an exact measure of glomerular filtration rate. However, the mannitol clearance presumably measures a constant fraction of the glomerular clearance in any one individual. Thus although absolute values for ionic reabsorption calculated from mannitol clearances may be too low, changes in ionic reabsorption are correctly indicated.

the three experimental periods. Effective renal plasma flow was determined by the *p*-amino-hippurate clearance in both subjects.

(c) The acute response of the kidney to acidosis was assessed in one subject in a 12 period experiment, during which a total of 10 gms. of ammonium chloride was ingested.

RESULTS

Acid-base equilibria of plasma and urinary ionic balances in acidosis

Data on the plasma composition and urinary ionic balance of subject P are summarized in Figures 1 and 2. In Figure 1 are presented the plasma values for chloride, bicarbonate, $p\text{CO}_2$, pH, sodium and phosphate. Each variable is referred to a base line established by averaging the five control determinations. Thus the mean

plasma chloride during the control period was 107 mEq per liter, varying within limits of 105 and 109 mEq per liter. In consequence of ingestion of ammonium chloride, the plasma chloride rose to a peak value of 122.8 mEq per liter on the fourth day of acidosis. In contrast the plasma bicarbonate fell from a mean normal value of 24.4 mEq per liter to 10.3 mEq per liter on that day.

Chloride and bicarbonate varied throughout in reciprocal fashion, the sum of the two remaining roughly constant for the first 11 days of the experiment. However, on the second recovery day, the sum of these two anions increased 6 mEq per liter, for bicarbonate rose more rapidly than chloride fell during this period. The sum of chloride and bicarbonate averaged 7 mEq lower than sodium during the control period and at the end of the recovery period. However, during the period of acidosis, sodium fell 2 to 3 mEq below the sum of these two anions. This finding can be partially explained by the decrease in base binding capacity of the plasma protein due to increased plasma acidity. However, this and other interesting results prompted a more complete ionic study of the plasma and urine in a second subject.

Respiratory compensation is shown by the drop in $p\text{CO}_2$ of arterialized venous blood from a normal value of 41.0 to 23.9 mm. Hg during acidosis; the latter value is indicative of a 70 per cent increase in alveolar ventilation over the normal. The subject was conscious of some increased ventilation at rest and obvious dyspnea on exertion. Presumably this increase in ventilation resulted from the increase in blood acidity from pH 7.40 to 7.25 (24).

The serum sodium concentration dropped significantly on the second day of acidosis and reached a low of 130.9 mEq per liter on the third day, a decrease of 8 mEq per liter. The plasma concentration of phosphate, in contrast, was maintained relatively constant until the fifth day of acidosis.

The concentrations of each of these plasma constituents with the exception of phosphate returned to normal or supra-normal levels within the five-day recovery period. Serum sodium and pH were restored first, bicarbonate and $p\text{CO}_2$ next, and chloride only on the fifth day. There

is evident an over-compensation in the return of bicarbonate, $p\text{CO}_2$, pH, and sodium to levels above those existing during the control periods.

In Figure 2 are summarized the rates of excretion of chloride, phosphate, titratable acid, ammonia and sodium, expressed in mEq per 24 hours; urine pH; body weight; and glomerular filtration rate and renal plasma flow on the five days on which these variables were measured. During the control period the rate of excretion of chloride averaged 130 mEq per day varying within limits of 107 and 151 mEq per day. In consequence of the ingestion of ammonium chloride and elevation of plasma level, chloride excretion increased to 368 mEq on the first day and to 458 on the third. During these three days there was a net loss of 230 mEq of chloride over and above that ingested in the diet and as ammonium chloride. At a mean concentration of 115 mEq per liter, this represents a loss of 2 liters of extracellular fluid in the first three days of acidosis. Body weight actually decreased 2.2 Kgm. during this interval. Although a rigorous analysis of these data cannot be justified, it is safe to infer that the major loss of weight early in this experiment resulted from loss of extracellular fluid.

The excretion of phosphate increased from an average of 41 mM per day during the control period to a peak of 60 mM per day on the third day of acidosis. Phosphaturia was not as significant a feature of acidosis in these experiments as in some previously reported (1). However, it accounted in large measure for the increased excretion of titratable acid from the mean control rate of 37 mEq per day to a peak of 68 mEq per day. The fall in urine pH from a control value of 5.7 to a low of 4.7 contributed, although less significantly than phosphate excretion, to the increased excretion of acid. Since increased excretion during the first four days of acidosis was attended by no fall in plasma level, phosphate must have been derived either from skeletal or intracellular stores. The fact that in subject H both calcium and potassium excretion were elevated during acidosis inclines us to the view that phosphate was derived from both possible sources.

The well known excretion of fixed base at the onset of acidosis, and its subsequent replacement with ammonia are well illustrated in this experi-

ment. During the control period, 142 mEq of sodium and 34 mEq of ammonia were excreted per day. On the first day of acidosis the excess chloride in the urine was largely neutralized with sodium, the rate of excretion of this latter ion rising to 310 mEq per day, whereas that of ammonia increased only to 62 mEq per day. By the fifth day ammonia had increased sufficiently to neutralize all excess chloride derived from the ammonium salt ingested, and the sodium balance became positive. On the first day of the recovery period the retention of dietary sodium was nearly complete, most of the urinary anions being neutralized by ammonia. A positive sodium balance was maintained for four days, during which time the alkali reserve and the salt content and volume of the several fluid compartments of the body were restored to their original condition.

During the five-day period of acidosis the net loss of sodium from the body amounted to 306 mEq. At a mean plasma sodium concentration of 135 mEq per liter this represents a loss of 2.3 liters of extracellular fluid. Actually body weight decreased during this interval by 2.9 Kgm. The extra weight loss probably represents intracellular fluid, for in subject H a significant loss of potassium was observed during the period of acidosis. It is, however, apparent that in this experiment roughly three-fourths of the weight loss can be ascribed to a reduction in volume of extracellular fluid. It is significant that in the first four days of recovery 309 mEq of sodium were retained to balance the 306 mEq lost during the period of acidosis. On the fifth day of recovery sodium excretion was exactly equal to the average of the five control days. Before this time body weight had been restored to normal.

A part of the fluid lost during the period of acidosis was derived from the vascular compartment, for the hematocrit, which fell steadily during the five control days, rose during the first three days of acidosis to a value appreciably above normal, to fall precipitously during the recovery period. In all some 1300 ml. of blood were drawn, relatively equally distributed over the 15 days of the experiment, so that a steady fall in hematocrit would be expected had no blood concentration resulted. No doubt because of this reduction in blood volume, glomerular filtration rate and renal plasma flow fell from their respec-

tive control values of 101 and 483 cc. per min. to 86.8 and 468 cc. per min. on the second day of acidosis, and to 92 and 402 cc. per min. on the fifth day. These changes in renal function are rather small, but had the dehydration been more severe and progressive it is probable that they would have been of greater magnitude. It must be remembered that the intake of food, fluid and salt was maintained at normal levels throughout the period of developing acidosis, a fact which must have reduced the severity of dehydration in comparison with that observed in patients suffering from diabetic ketosis or chronic nephritis, and exhibiting equivalent reduction in plasma alkali reserve. At the end of the recovery period both filtration rate and renal plasma flow had returned to levels slightly higher than those of the control period. Subject H who lost less weight and exhibited less dehydration suffered no decrease in filtration rate or in renal plasma flow; indeed both variables increased somewhat during acidosis. It is reasonable to infer that the dehydration which may accompany acidosis rather than the acidosis itself is the cause of the reduced renal function often observed (8, 25).

The results of the more extensive balance experiment performed on Subject H are summarized in Figures 3-5. In Figure 3 the plasma values for sodium, potassium, and calcium are presented in the left hand block, and those for chloride, bicarbonate, protein, phosphate, and sulphate are presented in the right hand block of each day's result. An undetermined moiety remains in the cation column which increases during acidosis from a control average of 6.2 mEq per liter to 10.0 mEq per liter on the last day of acidosis. The undetermined moiety is no doubt in part magnesium, and if one accepts a figure of 4 mEq per liter as a normal plasma value, the discrepancy during the control period is reduced to a satisfactorily small value. It must be remembered that the protein equivalence is calculated from total protein of serum and may well be subject to error. An increase in this error during acidosis may account for the additional slight discrepancy. On the other hand, as noted below, it may be in part due to an increase in plasma magnesium. During the control period total plasma anions average 158.2 mEq per liter. There occurred a slight decrease during acidosis to an

FIG. 3. CHANGES IN THE ELECTROLYTE PATTERN OF THE PLASMA OF SUBJECT H WHICH RESULTED FROM THE INGESTION OF 75 GMS. OF AMMONIUM CHLORIDE OVER A FIVE-DAY PERIOD

average of 156.9, rising again in recovery to 158.6 mEq per liter. Plasma sodium dropped from a control average of 141.2 mEq per liter to a low of 135.3 on the third day of acidosis, a decrease of 5.9 mEq per liter. This decrease is slightly less than that observed in subject P. Chloride, in consequence of the ingestion of ammonium chloride, rose from a control average of 109.8 mEq per liter to a peak value of 123.1 on the last day of acidosis, a rise of 13.2 mEq per liter. Conversely bicarbonate fell during acidosis from a mean control level of 26.3 mEq per liter to a low of 15.6 mEq per liter on the fourth day. Again as in subject P, the sum of chloride and bicarbonate remained roughly constant from day to day until the second recovery day when a moderate rise occurred due to the rapid return of bicarbonate to normal. The mean control value for the sum of chloride and bicarbonate was 136.1 mEq per liter, a value 5.1 mEq per liter lower than the control sodium level. This difference decreased during acidosis so that on the last day of this period it amounted only to 0.4 mEq per liter. As may be seen from Figure 3, this change in the proportion of sodium to the sum of chloride and bicarbonate may be ascribed in part to the slight increase in plasma potassium from a mean

control level of 4.26 mEq per liter to a high of 4.95 mEq per liter during acidosis, to the small reduction in phosphate from a control of 2.6 mEq per liter to a low of 2.1 mEq per liter on the last day of acidosis, and to the minor decrease in sulphate from an average of 1.1 mEq per liter to a low of 0.8 mEq per liter again on the last day of acidosis. The more significant change appears in the undetermined moiety and may represent some increase in plasma magnesium and possibly an error in the base binding power of the plasma proteins as noted above. Further investigation is needed to clarify this point. However, both subjects exhibited the same type of change in sodium/anion ratio to approximately the same degree.

The plasma pH averaged 7.41 during the control period and fell progressively during the period of acidosis to a low of 7.29, only to rise rapidly to a level of 7.41 on the second recovery day. An over-compensation then resulted with the pH increasing to 7.45 on the fourth and fifth recovery days. A similar over-compensation was observed during the recovery period with respect to sodium, calcium and bicarbonate levels.

Electrolyte excretion is graphically presented in Figure 4. Cation excretion is blocked against anion excretion for each day of the experiment.

All values are given in milliequivalents per 24 hours. In consequence of the ingestion of ammonium chloride, total ionic excretion (sum of anions and cations) rose steadily during the period of acidosis so that on the last day of this period a total of 1248 mEq per 24 hours were excreted as compared to a mean control value of 566 mEq. During the control period, the mean daily chloride excretion was 9 mEq higher than the mean sodium excretion, their values being 134.5 and 125.0 mEq per 24 hours respectively. However, with the ingestion of 15 gms. of ammonium chloride daily, chloride excretion rose progressively over the five-day period of acidosis to 470 mEq per 24 hours. Sodium excretion was greatest on the first day of acidosis and then fell in stepwise fashion from 293 to 50.6 mEq per 24 hours on the second day of recovery. Potassium excretion averaged 79.8 mEq per 24 hours during the control period, rose to a peak of 166.6 mEq per 24 hours on the third day of acidosis, and then fell gradually to a low of 20.9 mEq per 24 hours on the second recovery day. It is interesting that potassium excretion had not risen appreciably by the last day of recovery even though the net deficit incurred during the period of acidosis had been almost completely regained. Calcium

excretion rose to a high value of 41.4 mEq per 24 hours on the fourth day of acidosis from a mean control value of 17.6 mEq per 24 hours. In contrast to potassium excretion, the excretion of calcium remained above the control value during the recovery period, averaging 27.7 mEq for the six days of this period and falling to 24.8 mEq per 24 hours on the last day of the experiment. Magnesium excretion varied but little from a mean control level of 13.1 mEq per 24 hours reaching a maximum of only 16.8 mEq on the second day of acidosis and falling in the recovery period to a level only slightly below the control. With the drop in urine pH from a mean control level of 5.61 to an average of 4.92 during the period of acidosis, the capacity of creatinine to combine with acid became significant. Thus acid bound by creatinine rose from a mean control value of 3.8 mEq per 24 hours to a high of 10.1 mEq per 24 hours on the second day of acidosis. Sulphate excretion averaged 49.4 mEq per 24 hours during the control period, rising to 63.6 on the second day of acidosis and dropping to a low of 22.6 mEq per 24 hours on the first day of recovery. Phosphate excretion per 24 hours averaged several mEq greater than sulphate but behaved in a similar way. Organic acid excretion showed no

FIG. 4. CHANGES IN THE DAILY EXCRETION OF IONS OF SUBJECT H RESULTING FROM THE INGESTION OF 75 GMS. OF AMMONIUM CHLORIDE OVER A FIVE-DAY PERIOD

significant change during the experiment. Discrepancies between anion and cation excretion during the control and recovery periods are within limits of experimental error. During acidosis the increased discrepancy is unexplained, but might be due in part to the elimination of some undetermined organic cation, *e.g.*, a basic amino acid such as histidine.

In the central portion of Figure 5, base conservation, as represented by the excretion of ammonia and titratable acid, is plotted upwards while fixed base loss is plotted downwards. Again, it may be clearly seen that on the first day of acidosis the excess chloride in the urine was to a large extent neutralized by sodium. On the second and succeeding days, sodium excretion was spared not only by an increase in ammonia and titratable acid excretion but also by an increase in the excretion of potassium and calcium. During the last two days of acidosis and the early days of recovery, ammonia and titratable acid excretion

were sufficiently great to permit a progressive and significant decrease in all elements comprising fixed base. Attention is called to the gradual return of ammonia to the control level, for in this phenomenon lies the explanation of the restoration and over-expansion of the base reserves during recovery.

Daily urine output is graphed on an inverted scale immediately below fixed base loss in Figure 5. The increase in output during the period of acidosis is in large part the result of the increased intake of water to dilute the ammonium chloride ingested, for body weight decreased only by 1.4 Kgm. during the entire interval. Calculations of net loss of intra- and extracellular fluid during acidosis were less satisfactory in subject H than in subject P, because of less adequate dietary control and especially because of the relatively small change in body weight. Judging from the excess sodium and potassium excretion, loss of fluid was relatively equally distributed between the two compartments. Evidence of reduction in circulating blood volume either from plasma proteins or hematocrit such as that seen in subject P was nil. Accordingly no fall, and indeed an increase in glomerular filtration rate and renal plasma flow was observed. These increases are unexplained though they may be within limits of daily variation in this subject.

Ionic reabsorption in acidosis

It is obvious from a comparison of Figures 1 and 2, and of Figures 3, 4, and 5 that the increase in the excretion of chloride during ammonium chloride acidosis is related to the increase in plasma chloride concentration, and that the increase in excretion of sodium is the causative factor in the decrease in plasma sodium concentration and in the decline in body weight. Experiments in which glomerular filtration rate was measured permit a more exact description of the changes in renal function which underlie the altered excretion of the several ions. The significant data derived from 11 experiments performed at regular intervals on the two subjects during the control, acidosis, and recovery periods, are summarized in Tables I and II. Inasmuch as filtration rate decreased in one subject and increased in the second during acidosis, and since

previous work has shown that the quantities of sodium, bicarbonate, and chloride reabsorbed vary in proportion to glomerular filtration rate (22, 26, 27), the reabsorption and excretion of these ions have been expressed in mEq per 100 ml. of glomerular filtrate for comparative purposes. On the other hand, in Table I, the reabsorption and excretion of phosphate have been expressed in mM per min., for the capacity of the kidney to reabsorb this ion is fixed, limited and independent of filtration rate (28). The rates of excretion of titratable acid and ammonia are likewise expressed in mEq per min., for both hydrogen ions and ammonia are eliminated by mechanisms which are basically secretory in character, hence not related to filtration rate (29).

In Table I, it may be seen that in the two control experiments at a plasma concentration of 138 mEq per liter, 13.5 mEq of sodium were reabsorbed and 0.3 mEq were excreted per 100 ml. of glomerular filtrate. In the first experiment in acidosis although the quantity of sodium delivered into the renal tubules per unit volume of filtrate was less in consequence of the drop in plasma concentration, that lesser quantity was reabsorbed less completely than under normal conditions. Excretion rose to 0.45 mEq and reabsorption decreased to 12.9 mEq per 100 ml. of filtrate. Indeed decreased reabsorption and increased excretion must have been the major determinants of reduced plasma concentration and of loss of sodium from the body. By the fifth day of acidosis, the urinary loss of sodium had diminished to the control level, namely 0.29 mEq per 100 ml. of filtrate. No less than three factors contributed to diminished sodium loss: low plasma sodium concentration, *i.e.*, reduced sodium content of the filtrate; diminished chloride load demanding excretion, *i.e.*, intake of ammonium chloride had been cut from 15 to 10 gms. per day; and of greatest significance, increased substitution of ammonia for sodium in neutralizing urinary anions. We interpret the initial loss of sodium as the passive consequence of the increased excretion of chloride, brought about by the increased chloride load presented to the tubules. However, the reabsorption of chloride must be considered in relation to the reabsorption of bicarbonate, for previous work has shown that the mechanisms responsible for the salvage of these ions are inter-

related in such a way that decreased reabsorption of one ion species is *partially* compensated by increased reabsorption of the other (22). Since all urines were more acid than pH 6.0 the excretion of bicarbonate was negligible throughout the entire series of experiments. Because of reduced plasma concentration, less bicarbonate per unit volume of filtrate was presented for reabsorption in the two experiments in acidosis than in the two controls. Accordingly greater quantities of chloride were reabsorbed in acidosis than normally, *e.g.*, 10.9 and 11.2 mEq per 100 ml. of glomerular filtrate in acidosis, in comparison with 10.4 and 10.2 mEq normally. Yet because of the greatly increased load of chloride, even the enhanced reabsorptive capacity was exceeded, and chloride excretion rose. Over-compensation during the recovery period is evident in the reabsorption of a greater than normal quantity of bicarbonate, the reabsorption of chloride reverting more or less to the control value.

Diminished absorption and increased excretion of sodium during acidosis with compensatory over-absorption and diminished excretion during recovery are again evident in experiments on subject H presented in Table II. Thus in the second control experiments 13.71 mEq of sodium per 100 ml. of filtrate were reabsorbed and 0.12 mEq excreted. On the first day of acidosis 13.60 mEq were reabsorbed and 0.25 mEq were excreted. On the first day of recovery reabsorption had increased to 13.78 mEq and excretion had fallen to 0.036 mEq. These days are chosen for consideration because the plasma sodium concentrations were essentially the same on all. Such changes in absorption and excretion are small, but it is upon such small changes that the negative sodium balance early in acidosis and the positive sodium balance in recovery depend. For instance, a decrease in the absorption of sodium of 0.11 mEq per 100 ml. of filtrate would cause the loss of 250 mEq in a day's time at the filtration rate exhibited by subject H on the first day of acidosis. This would be equivalent to the loss of 1.8 Kgm. of extracellular fluid. The actual negative balance on this day was 168 mEq of sodium rather than the 250 mEq calculated, and the loss of weight was 1.4 Kgm. rather than 1.8 Kgm. One must infer either than the diminished absorption noted above was not maintained throughout

TABLE II
Rates of reabsorption and excretion of ions in subject H. on the first and fourth days of each of the three experimental periods

the 24 hours or that the filtration rate was lower at night (a reasonable assumption [30]). On the first day of recovery the increase in the absorption of sodium of 0.07 mEq per 100 ml. of filtrate over the last control period would cause the retention of 161 mEq in 24 hours and a gain of 1.2 Kgm. in weight. This quantity of sodium was not available in the diet and the actual sodium retention and weight gain were only one-third of the calculated values. A comparison of Tables I and II indicates that the greater sodium deficit, greater loss of weight and more significant fall in plasma sodium level in subject P as compared with subject H was the consequence of a greater increase in sodium excretion.

As shown in Table II potassium excretion increased sharply during acidosis, rising from a control average of 0.047 mEq per 100 ml. of glomerular filtrate to 0.091 mEq on the first day of acidosis and to 0.125 mEq on the fourth day of acidosis. On this latter day at the same plasma level as on the first control day, it is evident that the absorption per 100 ml. of filtrate was significantly diminished. Despite diminished absorption and increased excretion, plasma potassium was maintained at a nearly constant level, a fact explicable only on the assumption that the excess potassium was derived from cellular stores. Loss of intracellular potassium in acidosis has been adequately demonstrated (31). During recovery, potassium excretion dropped sharply to 0.020 mEq per 100 ml. of filtrate on the first day and to 0.012 mEq on the fourth day. This lower excretory rate during recovery must have been conditioned in part by the low plasma potassium level. In turn this low plasma level must have been caused by the restoration of depleted cellular reserves from the ingested and circulating moiety.

Depressed absorption of phosphate in acidosis is evident from the data of Table I. In the first experiment in acidosis 24 per cent of the filtered phosphate was excreted at a plasma concentration of 1.4 mEq per liter; in the second, 30 per cent was excreted at a significantly lower plasma concentration. In the control periods and following recovery only 5 to 10 per cent of the filtered phosphate was excreted. These results are in line with previous findings in man, namely, that acidosis depresses the tubular reabsorption of phosphate at normal plasma levels, although it

does not affect maximum tubular reabsorptive capacity at high plasma levels (32). The reduced plasma level of phosphate during recovery, like that of potassium, must have resulted from diversion of phosphate from plasma to cellular and osseous depots depleted during acidosis.

Early time course of renal compensations in acidosis

In order to study the time course of early renal compensations in acidosis a 12 period experiment was performed in which plasma and urine samples were collected at 15 min. intervals. During this experiment a total of 10 gms. of ammonium chloride was ingested in two doses. The significant observations are presented in Figure 6. The first two periods, performed with the subject in a state of normal acid-base balance, established control values for all variables. A 5 gm. dose of ammonium chloride was then ingested and following four additional clearance periods, another 5 gms. were taken.

Minimal changes in plasma chloride, bicarbonate and pH are evident within 7.5 min. after the ingestion of the first dose of ammonium chloride.

FIG. 6. CHANGES IN IONIC COMPOSITION OF THE PLASMA, IN RATES OF EXCRETION OF IONS DURING THE ACUTE PHASE OF A DEVELOPING AMMONIUM CHLORIDE ACIDOSIS

These changes became progressively more significant over the succeeding 45 min. Following the second dose, plasma chloride rose and bicarbonate, pH and sodium fell within the subsequent 90 min. to levels characteristic of moderately severe acidosis. A decrease in pH and an increase in content of titratable acid and ammonia are evident in the urine formed within 15 min. following the ingestion of the first dose of the acidifying salt, changes which were progressive throughout the course of the experiment. No significant changes in the excretion of phosphate, chloride and sodium were evident until the second 5 gms. of ammonium chloride were ingested, although plasma chloride rose appreciably during the interval between the two doses, a rise which was exactly counterbalanced by the fall in plasma bicarbonate. But following the second dose of the ammonium salt, chloride excretion increased, and since the excess urinary chloride was largely neutralized by sodium, the excretion of this ion increased proportionately. Only a part of the reduction in plasma sodium can be ascribed to increased excretion; the remainder must have been due to shifts of fluid and/or electrolyte between intra- and extracellular compartments.

One surprising finding in this experiment, which has been observed in others as well, was the prompt increase in the excretion of ammonia. It is usually stated that the kidney responds early to an increased acid load by excreting acid in free titratable form, and only after some delay, by excreting increased quantities of ammonia. It is evident from Figure 3 that ammonia and titratable acid excretion increased at equivalent rates and to approximately the same extent within the first 120 min. after the ingestion of an acidifying salt. It is true that this increase in ammonia output is only a small fraction of that attained after five days, but there certainly is no true delay in its onset, merely a gradual attainment of its maximal value. If it is correct to infer that no significant increase in plasma ammonia results from the ingestion of ammonium chloride (1, 6), then the observed increase in the rate of ammonia excretion constitutes a prompt renal compensation to ingestion of acid. Since plasma phosphate level did not change, the increased rate of excretion of phosphate during the latter half of this experiment resulted from diminished reabsorption. Both

the increase in the rate of phosphate excretion and the increase in the acidity of the urine contributed to the enhancement of titratable acid excretion.

DISCUSSION

It is apparent in ammonium chloride acidosis that the kidney maintains approximate constancy of total ionic concentration at the expense of ionic pattern and to a lesser degree at the expense of extracellular fluid volume. As bicarbonate is converted to chloride an increase in the tubular reabsorption of this latter ion species serves to restrict its loss, and thus the loss of base which accompanies it into the urine. For example, 10.3 mEq of chloride were reabsorbed and 0.28 mEq were excreted per 100 ml. of glomerular filtrate in the second control experiment presented in Table I. On the first day of acidosis increased quantities of chloride per unit volume of filtrate were delivered into the renal tubules, because of increased plasma concentration. However, an increase in reabsorption to 10.93 mEq per 100 ml. of filtrate limited excretion to 0.65 mEq. Had no increase in chloride absorption occurred, excretion would have increased to 1.36 mEq and the rate of sodium loss would have been tripled. It is apparent that an important renal response in ammonium chloride acidosis is the increase in tubular reabsorption of chloride, an increase which is more or less proportional to the extent of the conversion of bicarbonate to chloride. A consequence of this renal response is the maintenance of constancy of the sum of the plasma concentrations of chloride and bicarbonate despite considerable shifts in their relative proportions.

However, the conversion of a significant proportion of bicarbonate to chloride is attended by some increase in chloride excretion. Early in acidosis the excess urinary chloride is neutralized in large part by sodium derived from extracellular stores. This loss of fixed base is accompanied by the excretion of nearly equivalent quantities of water. Since the specific gravity of the urine of subject P averaged 1.016 during the five days of acidosis in contrast to 1.026 during the five control days, it is probable that the polyuria and consequent loss of weight during acidosis resulted from diminished posterior pituitary activity rather than from osmotic abstraction of body water by

concentrated urinary solutes. Indeed the probable stimulus promoting fluid elimination was the decrease in osmotic pressure of the body fluids in consequence of base loss. This is suggested by the fact that water excretion lagged somewhat behind base loss, for in both subjects plasma sodium level decreased significantly.

In subject P a major portion (three quarters) of the water and base sacrificed during acidosis was derived from the extracellular fluid compartment (*cf.* calculations on p. 426). In subject H balances were less accurate and calculations less dependable, but fluid loss seemed more equally divided between intra- and extracellular compartments. It is significant in subject H that the majority of the base lost on the first day of acidosis was sodium. However, by the third day potassium excretion had increased to a point where this ion neutralized a greater proportion of the urinary acid than did sodium. Since the plasma level of potassium did not change appreciably during acidosis, this ion must have been delivered into the blood from the tissues at essentially the same rate at which it was eliminated in the urine. The substitution of potassium for sodium in the urine permits the body to draw on the large intracellular reserves of buffer base; hence loss of interstitial fluid and reduction of circulating plasma volume are curtailed.

The changes in renal function described above are restrictive compensations, in the sense that they limit the disturbance of total ionic concentrations and volumes of both intra- and extracellular fluids. The elimination of titratable acid and especially of ammonia are corrective compensations in the sense that they permit the continued excretion of acid without further drain of base, and during recovery, rapidly restore ionic patterns, total ionic concentrations and volumes to normal. It is apparent from Figures 2 and 4 that ammonia excretion and to a lesser extent titratable acid excretion increased progressively over the five-day period of acidosis. In subject P, who ingested a smaller dose of ammonium chloride, the ammonia output on the fifth day was more than equivalent to the acid load, and a positive sodium balance was attained. In subject H, the ammonia output was sufficiently great to reduce the net loss of all components making up the fixed base of the urine, although positive balances were

not attained. In the early recovery period, the continued production of ammonia at a high rate permitted the rapid restoration of base reserves. The marked positive balance of sodium in subject P and of all components of fixed base except calcium in subject H is clearly evident in Figures 2 and 4.

Points of some possible therapeutic interest in clinical acidosis are the low plasma levels of phosphate and potassium observed during the recovery period despite the positive urinary balances. These low plasma levels undoubtedly result from the replenishment of depleted cellular reserves of potassium and phosphorus from circulating stores. Reductions in plasma levels of the magnitude observed in these experiments are inconsequential, but are in qualitative agreement with those of more significant magnitude observed following recovery from diabetic ketosis (13, 33).

The cause of the inverse relationship between chloride and bicarbonate reabsorption and the additional excretion of chloride and sodium in moderate and severe acidosis are interesting points for speculation. According to Walker *et al.* (34) the ionic pattern of the glomerular filtrate, which approximates that of the plasma, is rapidly altered during passage of the fluid through the proximal tubule. Although the sodium concentration is essentially unchanged, the chloride concentration of the residual tubular fluid rises as fluid is absorbed. One must conclude that sodium and water are reabsorbed proportionally, that chloride is absorbed infraproportionally to water, and that some other ion, most probably bicarbonate, is absorbed supraproportionally. According to Wesson *et al.* (30) the active absorption of sodium and its attendant anions in the proximal tubule is the origin of the osmotic force which causes the absorption of some 80 per cent of the filtered water in this segment. Possibly the tubule is relatively indifferent within narrow limits to the nature of the anion presented to it, *i.e.*, whether chloride or bicarbonate. Thus with moderate conversion of bicarbonate to chloride diminished absorption of the former might be more or less exactly compensated by increased absorption of the latter as a semipassive partner of sodium. However, the conversion of a significant proportion of the bicarbonate to chloride might be expected to reduce total anion absorption, for from Walker's data it

would appear that chloride absorption proceeds at a somewhat slower rate than bicarbonate absorption in the proximal segment. Reduction in total anion absorption in this segment would restrict cation (sodium) and water absorption to essentially equivalent degrees. The excess sodium over and above that normally absorbed in the distal tubule would be excreted in the urine. It is evident from Tables I and II that the magnitude of these changes is very small, a fact which renders their demonstration difficult. Nevertheless it is such small changes which underlie the negative sodium balance, diuresis and loss of weight which characterize ammonium chloride acidosis.

One is forced to the conclusion that such changes in glomerular filtration rate as occur in ammonium chloride acidosis cannot be directly responsible for changes in sodium and chloride balances. Thus qualitatively similar results in overall electrolyte balance were obtained in subjects P and H, yet in the former filtration rate fell and in the latter it rose. This fact alone, were it not supported by other evidence referred to in the first part of this paper, would justify correction of reabsorption to a standard rate of filtration for comparative purposes. This does not imply that a change in filtration rate may not modify the extent of a positive or negative balance by altering the quantity of electrolyte delivered into the distal segment of the renal tubule. Indeed there is evidence that such variations in filtration rate do alter electrolyte balance significantly (30).

That the increased excretion of ammonia and titratable acid in acidosis and for the first few days of recovery are compensations which restrict the loss of fixed base and restore the base reserves, is well recognized. Undoubtedly both serve to increase the distal tubular salvage of base, for the mechanisms for ammonia and acid excretion are both located at this site (35, 36). The former accomplishes the exchange of NH_4^+ ions for B^+ ions, the latter, the exchange of H^+ ions for B^+ ions (29). Thus in acidosis the delivery of additional base into the distal segment in consequence of diminished proximal tubular absorption is compensated by a greater exchange of H^+ and NH_4^+ ions for that base. Since as shown in Figure 6, the output of ammonia increases as rapidly as that of titratable acid following the

ingestion of ammonium chloride, it is reasonable to assign these increases to a single stimulus. Basically this stimulus appears to be a reduction in the quantity of bicarbonate delivered into the distal segment of the renal tubule, or more indirectly to a reduction in plasma bicarbonate concentration, for this latter factor largely determines the former in any given individual. According to views previously expressed there is a single transfer mechanism which exchanges H^+ ions for B^+ ions across the distal tubular epithelium (29). This mechanism is limited to some extent in transfer capacity and in the H^+ ion gradient which it can develop between blood and tubular urine. At normal plasma levels, that quantity of bicarbonate which reaches the distal tubule nearly saturates the exchange mechanism, *i.e.*, bicarbonate bound base is exchange for H^+ ion and carbonic acid is formed. The urine formed is only moderately acid and contains relatively small quantities of titratable acid, for the carbonic acid is largely dehydrated to CO_2 and water. Because of low acidity, little ammonia diffuses into the urine. At reduced plasma levels such as those observed in acidosis, little bicarbonate reaches the distal tubule. Fixed acid buffers are converted to titratable acid to the limit of the capacity of the kidney to establish an high hydrogen ion gradient. Because of high acidity of the urine ammonia diffuses from its site of formation in the distal tubular cells into the tubular lumen. This latter process, by reducing the hydrogen ion gradient between blood and urine permits the continued exchange of H^+ for B^+ ions. In essence, in the absence of sufficient bicarbonate or fixed buffer in the tubular urine to provide the requisite base to saturate the exchange mechanism, that base is derived from salts of strong acid by the substitution of ammonia as the neutralizing ion.

It is obvious that some factor other than plasma bicarbonate must condition the rate of excretion of ammonia, for ammonia output increased progressively during the five-day period of acidosis, although plasma bicarbonate had reached its lowest point by the third day. The nature and mode of operation of this factor is unknown at present.

SUMMARY

Ammonium chloride was given in divided dosage to two healthy adult subjects in order (a)

to relate the rates of excretion of the several ions to their respective plasma concentrations; (b) to determine the nature and extent of the changes in glomerular filtration, renal plasma flow, and ionic reabsorption which underlie altered excretory functions in metabolic acidosis; and (c) to study the time relations of the renal compensations to acidosis.

Following the ingestion of ammonium chloride, plasma bicarbonate fell in exact proportion to the increase in plasma chloride, so that the sum of these anions remained unchanged. During the recovery phase, plasma bicarbonate rose more rapidly than chloride fell, resulting in an increase in the sum of these anions. Although the ability of the renal tubules to reabsorb chloride increased as the load of bicarbonate presented in the filtrate was reduced, the increase was not sufficient to prevent loss of chloride in the urine. Early in acidosis the excess urinary chloride was neutralized for the most part by sodium derived from body buffers. Loss of sodium resulted in a moderate reduction of plasma sodium concentration which was limited by the excretion of nearly equivalent quantities of water.

Three different mechanisms were responsible for the restriction of sodium loss and the restoration of body buffer reserves: (a) following the ingestion of an acidifying salt, the increase in chloride reabsorption per 100 ml. of glomerular filtrate significantly diminished the loss of fixed base; (b) the increased excretion of potassium and calcium on the second and third days of acidosis permitted a decrease in sodium excretion although total fixed base loss increased; (c) ammonia and titratable acid production increased progressively during acidosis permitting the continued excretion of acid with a reduction in the loss of fixed base. A lag in the return of ammonia to normal during recovery resulted in an over-compensatory increase in plasma sodium and bicarbonate.

Despite the fact that glomerular filtration rate and renal plasma flow varied in opposite directions in the two subjects during ammonium chloride acidosis, sodium, potassium and chloride balances followed a similar pattern. Chloride reabsorption increased and sodium and potassium reabsorption decreased per 100 ml. of glomerular filtrate in both subjects. Despite the diminished absorption and increased excretion, plasma potas-

sium was maintained at a nearly constant level, thus indicating the release of intracellular stores of this ion. Phosphate likewise was released from either cellular or osseous stores.

Alterations in electrolyte pattern and balance during acidosis were also studied in acute experiments. It was observed that ammonia and titratable acid excretion increased at equivalent rates and to approximately the same extent within the first two hours after the ingestion of an acidifying salt. However, only a small fraction of the maximal rate of ammonia formation is attained within this time interval. The basis for the delay in attainment of the maximal rate of ammonia excretion early in acidosis and the persistence of a high rate of excretion during recovery is unexplained at present.

THE EFFECTS OF HISTAMINE ON RENAL FUNCTION IN HYPERTENSIVE AND NORMOTENSIVE SUBJECTS¹

BY F. C. REUBI² AND P. H. FUTCHER³

(From the Department of Internal Medicine, Washington University School of Medicine and Barnes Hospital, Saint Louis, Missouri)

(Received for publication June 16, 1948)

Little is known of the effects of histamine upon the renal circulation. According to Dale and Laidlaw (1), the rate of urine flow after the injection of histamine follows roughly the arterial blood pressure; their renal plethysmographic studies showed a decrease in the volume of the kidney, possibly due to active arteriolar constriction. These observations have generally been confirmed by other investigators (2-4), who found a reduced blood flow in laboratory animals and an oliguria in human beings. Following administration of histamine to human subjects, Bjering (5) noted a fall in the clearances of urea and creatinine which he ascribed to changes in renal circulation.

The favorable effect of antihistaminic drugs upon experimental nephritis in rabbits and on albuminuria and hematuria in certain cases of human glomerular nephritis suggests that histamine-like substances may cause the glomerular vasodilatation and increased permeability observed in the latter disease (6, 7). Some human subjects manifesting arterial hypertension of the "neurogenic" type (8) show a definite hypersensitivity to histamine and respond to the intracutaneous injection of a small dose with a so-called "diencephalic blush" (9). Because of these observations bearing on the influence of histamine upon renal and vascular disease, an attempt was made to investigate further the effect of histamine upon renal function. We describe below the influence of a subcutaneous injection of histamine upon renal function as measured by the clearance technique.

¹ This investigation was supported by a grant-in-aid from the National Institute of Health, United States Public Health Service.

² Fellow of the Swiss Foundation for Medical and Biological Research. Present address: The Medical Clinic, University of Berne, Berne, Switzerland.

³ Present address: Dept. of Medicine, The Johns Hopkins Hospital, Baltimore.

SUBJECTS AND METHODS

Experiments were performed upon five patients with essential hypertension without ascertainable antecedent renal disease, and upon five normotensive patients.

Mannitol and para-aminohippurate (PAH) were measured in blood and urine during five or six consecutive periods of 10 to 20 minutes duration. After a priming dose had been administered, the blood levels of mannitol and PAH were maintained approximately constant by intravenous administration of a 0.9% sodium chloride solution containing these substances, at a rate of 4 cc. per minute. Urine was collected by catheterization, and the bladder was rinsed with 0.9% sodium chloride solution at the end of each period. The analytical procedures used were essentially those employed by Goldring and Chasis (10).^{4, 5} Among factors considered in performing the plasma and urine mannitol blanks were non-fermentable reducing substances contributed by plasma or urine, or "Factor 1," reducing substances contributed by the yeast suspension, or "Factor 2," and adsorption or destruction of mannitol by the yeast suspension, or "Factor 3." In performing the plasma blank, all three factors were corrected for, save in the case of the three subjects, L. C., I. H., and M. L., when compensation was made only for Factor 1. In performing the urine blank, Factors 2 and 3 were corrected for, save in the case of the same three subjects, when compensation was made only for Factor 2. Data on the technique employed for these blank determinations will be presented elsewhere (11).

The renal plasma clearances of mannitol and PAH were calculated using the formula "UV/P," where "U" and "P" are respectively concentration of the substance in urine and plasma, and "V" the volume of urine excreted per minute expressed in cubic centimeters (12). The value of P at the exact midpoint of each period was calculated by interpolation between the values observed during each period. The "filtration fraction" was calculated as the ratio of the mannitol clearance to the PAH clearance.

The afferent and efferent arteriolar resistances (R_A and R_E) were computed from our data according to Lam-

⁴ The mannitol and PAH solutions administered were generously contributed by Sharpe and Dohme Company; the starch-free baker's yeast used in the mannitol analyses was given by Anheuser-Busch, Inc.

⁵ Miss Ellabeth Houghton, Mrs. Mattie Heady and Mrs. Harriet Weil rendered technical assistance in performing and reporting the investigations.

§ R_E = efferent arteriolar resistance in mm. of mercury per cc. renal plasma flow per minute.

port's formulae (13). In these computations we arbitrarily assumed a hematocrit of 0.43, a plasma protein concentration of 7.0 grams per 100 cc., and a ratio of albumin to globulin of 2.2. The injection of histamine did not influence the hematocrit values in the two experiments in which the measurement was made.

In addition to the 10 clearance experiments, the renal extraction of PAH and mannitol before and after subcutaneous administration of 0.5 mgm. of histamine was determined in three subjects by catheterization of the right renal vein,⁶ using the technique devised by Courmand and Ranges (14) for the heart and developed by Warren, Brannon and Merrill (15) for the renal vein.⁷ The

⁶ The assistance of Dr. H. A. Schroeder in performing the catheterizations is gratefully acknowledged.

⁷ Experiments in which clearance measurements and renal venous catheterizations were performed simultaneously showed a definite discrepancy between the mannitol

blood pressure was measured in the arm by the auscultatory technique.

The dose of histamine was chosen so as to elicit a moderate general reaction with flushing of the face and headache. Lachrymation, palpitation, and tachycardia occurred in some patients; the blood pressure fell regularly only in hypertensive subjects. Usually 0.3 to 0.5 mgm. of histamine, calculated as the pure base, was administered, depending on body weight; in one case (F. W.) a marked reaction was produced by 0.15 mgm., and in another (L. C.) the administration of a total of 0.7 mgm. in two doses resulted in almost no reaction and no striking changes in renal clearances. The histamine

clearance as usually calculated (UV/P) and the clearance computed from the calculated renal blood flow and the observed renal extraction of mannitol (23). However, we assume that for our purposes the clearance methods permit a useful approximation of kidney function.

was administered subcutaneously as the acid phosphate in a solution containing 1 mgm. of the pure base in 1 cc. Renal clearance measurements were made for two or three control periods before injecting histamine.

RESULTS

The most constant changes in renal clearances after the injection of histamine were a decrease, as indicated by the PAH clearance (16), in the plasma flow and an associated increase in the filtration fraction. The filtration rate, as measured by the mannitol clearance (17), was not consistently altered (Tables I, II). These characteristic features are summarized in Table III. In Figure 1 are presented schematically the mean values observed in both the hypertensive and non-hypertensive groups. In the normotensive subjects,

there appeared to be no correlation between the reduction in renal plasma flow and the systemic blood pressure, the latter showing a very variable behavior. The frequent elevation in the filtration fraction in both groups of subjects indicates that active arteriolar constriction occurred. It has been generally assumed that spasm of the efferent arterioles accounts for this elevation of the filtered portion of plasma passing through the kidney (18) Whereas four out of five hypertensive individuals showed a definite rise in the filtration fraction, such an elevation was evident in only two normotensive subjects; in two others it was questionable, occurring slowly possibly because of spontaneous changes in arteriolar tone unrelated to the injection of histamine (18). In one hypertensive subject and one normotensive subject

there were no changes in filtration fraction. The average curves (Figure 1) indicate that the mean increase in filtration fraction was about the same in both series, amounting to 12% in the normotensive group and 14% in the hypertensive patients. Two normotensive individuals appeared to be very sensitive to the injected amine.

The calculated efferent arteriolar resistance was increased in four and unchanged in one hypertensive subject. It was also increased in four (in three only slightly) and unchanged in one normotensive individual. The afferent arteriolar resistance was decreased in three and unchanged in two hypertensive patients; in normotensive subjects, changes were roughly parallel to those in the efferent resistance.

As will be seen in Table IV, the renal extraction percentage of mannitol and PAH was not consistently influenced by the injection of histamine. The data on subject F. C. presented in Tables II and IV were obtained during the same experiment.

Qualitative (heat) tests on the urine of nine of the ten patients revealed no proteinuria occurring during the clearance period immediately following the injection of histamine. The tenth patient (I. H.) exhibited traces of urinary protein antecedent to the injection of histamine; the injection caused no immediate increase in proteinuria.

FIG. 1. SCHEMATIC PRESENTATION OF AVERAGES FOR RENAL CLEARANCES AND FILTRATION FRACTION (FF)

Broken line presents data on five hypertensive subjects (Table I); solid line on five normotensive subjects (Table II). Histamine injected at start of third period. Clearances of para-aminohippurate (PAH) and mannitol (M) expressed as cc. plasma per minute.

DISCUSSION

From these observations it would appear that the reduction in renal plasma flow following the subcutaneous administration of histamine was often due to efferent arteriolar constriction. In some cases (M. S., J. R.), in whom there was observed no change in filtration fraction, it seems likely that constriction of the afferent arteriole took place. The fall in systemic blood pressure may have played a part in reducing renal plasma flow in patient L. C.

It is known that histamine may produce vasoconstriction of arterioles, but constriction alone, wherever it might take place in the kidney, would hardly account for the absolute increase in the mannitol clearance simultaneous with a fall in systemic blood pressure observed in two hypertensive patients (I. H. and M. L.). With efferent arteriolar constriction, if relaxation of afferent arteriolar tone or increased permeability of glomeru-

lar endothelium did not occur, one would expect little change in or a reduction of the filtration rate. The occurrence of afferent arteriolar relaxation seems to be supported by the experiment on patient I. H. presented in Table I. In the third period there was no change in the mannitol clearance, but blood flow was significantly reduced. This finding can be related to efferent arteriolar constriction. After the second injection of histamine at the start of the fourth period, however, there was a sudden increase in both PAH and mannitol clearances, the former reaching its previous level, the latter rising markedly above it. As the filtration fraction remained practically unchanged concurrent with these increases, relaxation of afferent arterioles can be considered as probably responsible for this phenomenon. Further evidence in favor of this view is found in the values for efferent and afferent arteriolar resistance; the former increased during the third period, the latter decreased during the fourth. Change in permeability of glomerular endothelium could not of itself account for the observed increase in the PAH clearance. As regards possible increased glomerular permeability, it is of interest that the slight proteinuria observed in this patient before histamine was administered did not increase.

A significant increase in the filtration rate without simultaneous reduction of renal blood flow was also evident in subject M. L. (Figure 2). Here again two interpretations are possible—efferent arteriolar spasm plus afferent relaxation, or increased endothelial permeability. The first possibility seems to be enhanced by the behavior of efferent and afferent resistance, since the former increased from 0.0084 mm. of mercury per cc. of plasma per minute to 0.0109 and the latter decreased from 0.0825 to 0.0542. It is worthy of emphasis that this absolute increase in the filtration rate did not occur in any of our normotensive subjects, suggesting that the glomerulus of the hypertensive kidney may react in a characteristic manner.

We therefore interpret our data bearing on the state of the afferent glomerular artery as indicating that in some subjects the administration of histamine produces constriction, and in others either no effect on, or relaxation of, this vessel. Relaxation was observed only within the hypertensive group of subjects.

There was no consistently pronounced effect of the injection of histamine upon the urine volume. Changes in the reabsorption of water seemed to occur spontaneously, more or less independently of the filtration rate. Data obtained from analysis

FIG. 2. EFFECT OF HISTAMINE UPON RENAL FUNCTION OF HYPERTENSIVE SUBJECT M. L.

Abbreviations and units as in Figure 1. Blood pressure (BP) expressed as mm. mercury, and urine flow (U) as cc. per minute.

of renal venous blood (Table IV) indicate that the extraction of PAH was not reduced after histamine, so that impairment of tubular function, which might explain a fall in PAH clearance, seems unlikely.

Our findings indicate that the kidney of hypertensive subjects does not appear to be on the whole much more sensitive to the action of histamine than that of normotensive subjects, at least in this small series. Moreover, individual susceptibility seems to vary widely. Noteworthy perhaps is the different behavior of the afferent arteriolar resistance in both groups. The average efferent resistance was increased from 0.0068 to 0.0088 in the normotensive and from 0.0155 to 0.0216 in the hypertensive subjects. The average afferent resistance rose after histamine from 0.0208 to 0.0249 in the normotensive but fell from 0.0995 to 0.0878 in the hypertensive group. This fall is possibly related to the fact that R_A is already very high in the latter group (19).

It is uncertain whether the observed effects upon renal physiology were due to histamine alone, or whether the action of epinephrine was involved. It is conceivable that in our experiments the administration of histamine, itself possibly inactive upon the kidney, induced a response due to adrenalin; such an effect of histamine may occur in patients with pheochromocytoma (20, 21). There is little doubt that the effects of histamine upon renal arteriolar tone are similar in some respects to those of epinephrine.

The reaction of the efferent arteriole to histamine must be emphasized, as it is elicited in this case by a so-called "hypotensive" amine. It appears that various drugs are capable of inducing an elevation in filtration fraction similar to that found persistently in hypertensive subjects.⁸

The possibility that histamine may play a part in the pathogenesis of glomerular nephritis has already been referred to. If the action of histamine is involved in the etiology of the disease, on the basis of our observations it might be expected that the filtration fraction would be found to be higher than normal. Earle *et al.* (22), however, observed an abnormally low filtration fraction in glomerular nephritis. The two patients studied by those authors who were in initial stages of their disease had manifested symptoms for three and five weeks. At this stage alterations of the capillaries may have reduced the "filtering bed." Studies performed during the very first days of the disease would provide a more acceptable basis for evaluating the possible role of histamine in its pathogenesis.

SUMMARY

1. The effect of a subcutaneous injection of histamine upon renal function was investigated in five hypertensive and five normotensive subjects

⁸ In an additional patient with hypertension studied after this work had been completed, a large dose of histamine (0.5 mgm.) produced a dramatic reaction with pallor and palpitation. The filtration fraction decreased from 0.256 to 0.100 consequent to a fall in mannitol and an elevation in PAH clearance. These findings suggested efferent arteriolar relaxation, or, as the urine flow was markedly reduced, a back diffusion of mannitol through the tubular walls. Blood pressure was not measured. Although this picture was observed only in one instance, it indicates how the effects of the same drug may vary with the susceptibility of the patient.

with the aid of measurements of the mannitol and para-aminohippurate clearances.

2. Four of five hypertensive subjects responded with an increase in the filtration fraction and efferent arteriolar resistance, probably caused by a constriction of efferent glomerular arterioles. In two of the four patients, this constriction was accompanied either by relaxation of the afferent glomerular arteriole (decreased afferent resistance), or, less likely, by increased glomerular permeability. In the fifth subject there occurred a proportional reduction of renal blood flow and filtration rate in spite of decreased afferent resistance, probably related to a fall in blood pressure.

3. In four of five normotensive patients, there were observed manifestations of efferent and afferent arteriolar constriction. One normotensive subject showed no change in renal clearance following administration of histamine.

4. Significant changes in the urine volume were not regularly observed.

5. The renal extraction of para-aminohippurate did not change after administration of histamine in three subjects.

STUDIES OF COPROPORPHYRIN. I. THE PER DIEM EXCRETION AND ISOMER DISTRIBUTION OF COPROPORPHYRIN IN NORMAL HUMAN URINE¹

By CECIL JAMES WATSON, VIOLET HAWKINSON, SAMUEL SCHWARTZ,
AND DONALD SUTHERLAND

(From the Department of Medicine, University of Minnesota, Minneapolis)

(Received for publication July 9, 1948)

A recent review (1) has dealt with previous studies of the urinary coproporphyrins, both as carried out in this laboratory and elsewhere. The purpose of the present series of communications is to provide newer data relating to various aspects of the coproporphyrin problem.

It is well known that two of the four coproporphyrin isomers occur in human urine (1). These naturally occurring isomers are types I and III according to H. Fischer's classification, as based upon the configuration of the four artificial aetioporphyrins (2). Apart from the difference displayed by the two isomers in ester melting point and crystal habitus, a differing physical behavior has been described as manifested in their pH fluorescence curves. This difference was first noted by Hoerbarger and Fink (3-5) who attempted to apply it to the coproporphyrin of normal urine. The crystal habitus and pH fluorescence curve of the few crystals which they obtained indicated the presence of coproporphyrin I (5). A later study by Watson (6) was likewise somewhat indecisive in that the melting point of the crystalline ester was 228° C, that of pure coproporphyrin I methyl ester being 252° C (corrected), as contrasted with the varying or dimorphic melting point of the esters of coproporphyrin III: 134°, 142°, 168° (2). The crystal habitus in this study also, was that of the type I isomer, and it was therefore concluded that in the urine employed, which was from one normal individual, the preponderant coproporphyrin was type I. At the same time it was believed that a small amount of the type III isomer was present, since a few rosettes of prisms having the type III habitus were obtained from the mother liquor. The weighed yield of crystals in

this study was 0.13 mgm., obtained from 33 liters of urine. This had seemed a fair sized undertaking, but it was dwarfed by the subsequent investigation of Grotepass (7), in which 10,000 liters of presumably normal human urine were worked up with a yield of ca. 200 mgm. of crystalline coproporphyrin ester. Grotepass' method was to adsorb the porphyrin on infusorial earth, large containers being employed into which many individuals passed their urine, the urine simply being decanted after a period of contact with the earth. The porphyrin which was isolated after subsequent purification and fractional crystallization was found to consist of about equal parts of type I and III isomers, and it was therefore concluded that the normal urinary coproporphyrin consists of approximately equal parts of the two types. Certain reservations regarding this conclusion will be discussed subsequently.

During the past nine years studies have been in progress which were designed to provide a method of isomer analysis applicable to a small volume of urine and by means of which it would be possible to make a systematic study of the urinary coproporphyrin isomer excretion without recourse to isolation of the crystalline esters. A multitude of possibilities were explored relating in the main to differential solubilities, such as that of the methyl esters in cold methyl alcohol (8) or absolute ethyl ether (9), also to differential chromatographic behavior with various solvents and adsorbents. It was previously reported (10) that pure coproporphyrin III methyl ester was readily eluted from aluminum oxide (Brockmann) by 30% aqueous acetone, while the type I ester remains adsorbed, being eluted with pure acetone. After extensive preliminary purification this method was applicable only to the porphyrin from certain urine samples. A great many alternative preliminary treatments were tried in the hope that

¹ Aided by grants from the John and Mary R. Markle Foundation, New York City, and from the Medical Research Fund of the Graduate School, University of Minnesota, Minneapolis.

one might be found which would be uniformly applicable, but none were satisfactory. During these investigations, however, a new difference in physical behavior was discovered, *i.e.*, that the red fluorescence in ultraviolet light exhibited by the type I methyl ester rapidly disappears in 30–35% aqueous acetone, in the cold, while that of the type III ester persists (11). This phenomenon has been shown to be due to a differential rate of precipitation (12). It has been made the basis of two alternative procedures for analysis of isomer distribution, A and B, which have been described in detail in separate communications (11, 12).

In the present study these procedures have been applied to a series of 24 hour urine samples from presumably normal healthy adults, in order to determine both total coproporphyrin and isomer percentage.

MATERIAL AND METHODS

Twenty-four hour urine samples were studied from 53 individuals. Thirty of these ranged in age from 19–30, ten from 30–64, and 13 from 65–86. Twenty-eight were males and 25 were females. Those between 19 and 30 in age were medical students, interns, technicians and physicians. Some of these undoubtedly had mild chemical exposure of the type encountered in a routine clinical laboratory, plus in a few instances, fumes of petroleum ether, ethyl ether, chloroform, and benzene, but in no instance was this believed to be of consequence. So far as can be determined, heavy metal exposure and alcoholism were excluded in the entire group, and there was no history of any chemical exposure in the older members of the group. The 24 hour urine samples were collected in large bottles without preservative.

Twenty-four hour urine samples were also collected from two groups of students in the Divinity School of the University of Chicago, the first a group of nine during May 1946, the second a different group of ten individuals during February 1948.² Total coproporphyrin concentration and isomer distribution were likewise determined for each of these samples.

The method employed for the quantitative determination of the total coproporphyrin and isomer percentage has been described in detail elsewhere (12). Procedure A of the two alternative procedures, was used in the first 30 instances (individuals from 19 to 30 years of age). In addition procedure B was applied to aliquots of the same 24 hour urines from 18 of these individuals. Procedure B is somewhat simpler and less liable to error than A. Repeated determinations carried out on the same

urine samples with the two procedures, have shown excellent agreement, as will be evident from data presented below.

As noted in an earlier paper (12), the fluorescence measurements have been made in a Klett fluorophotometer, using a fluorescein solution for the balanced photo cell. In this paper a typographical error unnoticed in correction of the proof, indicates that the fluorescein concentration is 3 Gm.%, whereas the correct value is a 3 mgm.%. This is an arbitrary concentration in any event which would have to be calibrated for any given instrument, against known concentrations of pure coproporphyrin.

Recently one of us (S.S.) has devised a simpler method for determination of the total urinary coproporphyrin, applicable to 5 cc. of urine. The results obtained with this procedure indicate that the true values for the UCP are approximately 20% higher than those obtained with the method (12) employed in the present study. This work will be described in a separate communication.

RESULTS

The results of the duplicate determinations with procedures A and B are given in Table I. From this it is evident that the two procedures are in good agreement.

The data for the 53 individuals are given in Table II. As will be noted this table includes the values for the total urinary coproporphyrin (UCP) and the percentage of the two isomers. The frequency distribution of the UCP, and of each of the isomers, I and III, is shown in Figure 1.

The data for the Chicago Divinity students are given in Table III.

² We are indebted to Miss Elaine Katz of the Argonne National Laboratory, Chicago, for obtaining and sending us these samples.

ponderant in normal human urine. They do not support Grotepass' conclusion (7) that the type III isomer composes approximately half of the normal urinary coproporphyrin. As pointed out by Dobriner and Rhoads (13), Grotepass' study is subject to the criticism that if but one abnormal individual contributed to the pooled urine which he studied, an erroneous conclusion might easily have been drawn with respect to the entire group. In a later paper of this series two cases will be described in some detail in which a latent, entirely symptomless, idiopathic coproporphyrinuria exists. These individuals' 24 hour urines usually contain 1-4 mgm. of coproporphyrin III. Similarly, an individual with latent plumbism excretes markedly increased amounts of coproporphyrin III, not infrequently ranging from 0.5 to 1.5 mgm./day.³ Thus, in a study of the type conducted by Grotepass, it is evident that a considerable error might be introduced by a relatively small contribution of urine from one or more individuals with latent or unrecognized abnormality. Nevertheless, a "geochemical" difference must also be considered and, in fact, the recent study by Schwartz and his associates (14) in Chicago offers support for such a possibility. In this study the urines of a "control" or supposedly normal group of individuals were regularly found to contain more than 50% of the type III isomer, usually from 60 to 85%. It was at first believed that this might be accounted for by occupational chemical or heavy metal exposure.

³ Unpublished data.

DISCUSSION

The present results are in accord with the earlier indications of Hoerbarger and Fink (3, 4), and of Watson (6) that the type I isomer is pre-

FIG. 1

or use of alcohol, but later members of the group who exhibited the same increases of the type III isomer were students in the Divinity School who had no known exposure to metals or chemicals which might produce abnormality.

In order to be doubly certain on this point, samples were collected in May 1946, from a group of nine of these students (Group 1 in Table III), and were sent to this laboratory for the isomer analysis with the results which have been given in Table III. These may be contrasted with data obtained in February 1948, from another group of 11 students at the same school. Unfortunately, it was not possible to obtain samples again from any of the individuals of the 1946 study. There is every reason to assume, however, that the habits and environment of the two groups were essentially the same. The only known difference of possible significance was the installation of a new city water filtration system for that area of Chicago, early in 1947. Thus there is the possibility that a change in water supply was responsible for the rather striking reversal in isomer-ratio noted in Table III. Other possibilities, however, are not

excluded, and further studies in other areas, both urban and rural, would be of interest with relation to such factors as water supply, air contamination and occupational or environmental chemical exposure.

In the meanwhile it is evident from the present data that a preponderance of the type I isomer is characteristic of normal adults in the Minneapolis area. It is believed that this should be regarded as the norm, since it is well established that heavy metal or chemical intoxication even though of such mild degree as to be symptomless, nevertheless causes significant increases of the type III isomer. This will be considered in a subsequent paper, in relation to the effect of alcoholism. The phenomenon of reversal of the isomer ratio within a normal total value, has been noted in certain of the "control" personnel studied by Schwartz and associates (14). The relative or even absolute decrease of type I isomer in these instances points to a closer relationship between the two isomers than hitherto entertained. Although not necessarily reciprocal, the relationship appears to be one of a balanced production normally favoring type I, but

easily upset in favor of type III by chemicals, metals and possibly other factors which will be discussed in subsequent papers.

In so far as the study of any given individual or group of cases in one area is concerned, it is recognized that before conclusions could be drawn as to the significance of reversal of the isomer ratio, it would be necessary to establish the ratio for presumably normal individuals in that area. With the method used (12), it is believed that where increases above a total of 100 γ are encountered, values of 40% or more of type III isomer may probably be regarded as abnormal even though control data for that area are not available.

In animal studies it is likewise possible that local differences will be found to prevail. Our own observations (in both Minneapolis and Chicago) have thus far indicated that the type III isomer comprises about 80% of the total in urine from healthy rabbits, and about 50% from that of healthy dogs. Whether this higher ratio of type III is due to metal or chemical contamination of the diet, as for example, from the cages, has not been determined.

SUMMARY AND CONCLUSIONS

1. The total urinary coproporphyrin (UCP) and the isomer distribution have been studied by means of the differential precipitation, or "fluorescence quenching" method, in 24 hour urine samples of 53 presumably normal adult humans of both sexes, living in Minneapolis and ranging in age from 18 to 86.

2. The UCP in this group ranged from 17 to 99 γ /24hrs., with an average of $55.2 \pm 2.87 \gamma$.

3. The percentage of type III isomer was 40 or higher in five of the 53 individuals. In three of these it was from 46 to 52%. In 48 it was less than 40% and of these, 43 were below 35%. In terms of gamma/day the type III isomer ranged from 1.3 to 34.4, with an average of $14 \pm 1.14 \gamma$.

The type I values ranged from 14.5 — 89.1 γ with an average of $42 \pm 2.1 \gamma$.

4. Twenty male Divinity students, living in the area of the University of Chicago, were also studied as to total UCP excretion and isomer distribution. Samples from the first group of nine were

obtained in May 1946. These contained from 58 to 82% of type III isomer within a normal value for total UCP. The second group of 11 was studied in February 1948; in these the range was 56 to 88% of type I isomer. The possibility is considered that a change in the water supply in 1947 may explain the return to the normal ratio.

STUDIES OF COPROPORPHYRIN. II. AN INVESTIGATION OF THE CONTRIBUTION TO THE URINARY COPROPORPHYRIN OF HEMOGLOBIN AND OF BACTERIAL METABOLISM IN THE INTESTINAL TRACT^{1, 2}

BY EVREL A. LARSON AND CECIL JAMES WATSON

(From the Department of Medicine, University of Minnesota Hospital, Minneapolis)

(Received for publication July 9, 1948)

Stokvis (1) advanced the idea that blood in the intestinal tract was the source of the urinary porphyrin. Schumm (2) also held this belief. Subsequent studies, notably those of Fischer and Hilmer (3), Brugsch (4, 5), and Kaunitz (6) indicated that a variable fraction of the urinary coproporphyrin was thus derived. The presence of a porphyrin in meconium (2, 7, 8), later identified by Waldenström as coproporphyrin I (9), together with a number of other evidences of an endogenous formation, which are discussed in detail in recent reviews (10, 11), have made it reasonably clear that at most not more than a certain fraction of the urinary coproporphyrin (UCP) could be regarded as originating in the intestinal tract. The purpose of the present investigation was to obtain more definite information as to the size of this fraction, under various experimental and clinical conditions. It was also determined to study the relative percentage of coproporphyrin isomers composing any increases which might be observed, since previous studies bearing on these questions had dealt only with the total coproporphyrin. It was conceivable on *a priori* reasoning, that any one or a combination of the following might alter the total coproporphyrin concentration or the isomer distribution in the urine:

(1) A formation of coproporphyrin III from hemoglobin, by the bacterial flora of the colon, with reabsorption and excretion in the urine. Jakob (12) showed that pure cultures of *E. coli* produce small amounts of coproporphyrin III in the presence of hemoglobin. Snapper (13-15)

had previously shown that hemoglobin is converted in small part to protoporphyrin in the colon, and Kämmerer (16) ascribed its formation to a symbiotic activity of the bacterial flora. Hill and Holden (17) showed, however, that pure cultures of *E. coli* liberated free protoporphyrin from hemoglobin; this was confirmed by van den Bergh and co-workers (18). No direct evidence has been described, however, for the intestinal formation of coproporphyrin III from hemoglobin, although the above-mentioned work of Jakob's suggested that this might take place. In a previous study (19), it was shown that in the presence of complete biliary obstruction due to cancer, coproporphyrin could not be demonstrated in the acholic feces even when there was bleeding into the upper gastrointestinal tract. This observation does not favor an origin from hemoglobin in the bowel, but the possibility could not be excluded that coproporphyrin thus formed had been entirely reabsorbed.

(2) A formation of coproporphyrin, either I or III, as an independent bacterial synthesis in the absence of hemoglobin. Fischer and co-workers (3, 20) demonstrated that yeast cells undergoing autolysis, synthesize coproporphyrin I. Kench and Wilkinson (21) have recently shown that yeast cells elaborate both isomers, the preponderance depending on the conditions of the culture. Coulter and Stone (22) found that diphtheria bacilli in broth cultures form coproporphyrin in an amount roughly proportional to that of the toxin produced. Gray and Holt (23) have recently demonstrated that this is the type III isomer and that it is formed in relatively large amount under suitable conditions of growth. All of these observations suggested that the bacterial flora of the human colon might, at least under certain circumstances, produce either coproporphyrin I or III, and, if it were absorbed, might thus bring

¹ Aided by grants from the John and Mary R. Markle Foundation, New York City, and the Medical Research Fund of the Graduate School, University of Minnesota, Minneapolis.

² A portion of this study was included in a thesis submitted (by E. A. L.) in partial fulfillment of the requirements for the Ph.D. degree, University of Minnesota.

about an increased urinary excretion of the corresponding isomer. von Mallinkrodt-Haupt (24) has, in fact, postulated that the urinary coproporphyrin is wholly related to the bacterial flora in the colon, and that the increases described in pernicious anemia are related to the effect of achylia in altering the flora. It will be seen subsequently that the evidence in favor of this theory is indeed very meager.

(3) The further possibility had to be considered that liver function plays an important role with respect to coproporphyrin I or III, which might originate in the intestinal tract whether from hemoglobin or bacterial metabolism. Kaunitz' study (6) suggested that coproporphyrin is absorbed from the intestine but that it does not appear in the urine in appreciable amount unless there is associated liver functional impairment. Thus, after oral administration of 20 Gm. doses of crystalline hemoglobin, significant increases of urinary coproporphyrin were observed only in cases of liver disease, or in instances where liver injury was postulated as a result of severe anemia or toxemia. Kaunitz assumed but did not prove that

the increases which he noted were composed of type III isomer, derived from the fed hemoglobin. Kaunitz (6) and Boas (25, 26) described increases of urinary coproporphyrin following gastrointestinal bleeding due to peptic ulcer or malignancy. This increase was likewise assumed to be composed of the type III isomer, although it was not isolated. There is also the possibility that some degree of liver functional impairment had occurred with resultant increase of type I rather than type III, an association which has been discussed previously (11), and in favor of which there is abundant evidence in the literature (5, 10, 27-29). It seems less probable, however, that this factor would be important after the simple ingestion of blood by normal individuals, which was reported by Schumm (2), and Fischer (3) to be followed by an increased urinary coproporphyrin of undetermined type. This was not confirmed by other investigators (14, 15, 30, 31), nor were Borst and Königsdörffer (32) able to detect the appearance of any porphyrin in the blood plasma after ingestion of coproporphyrin.

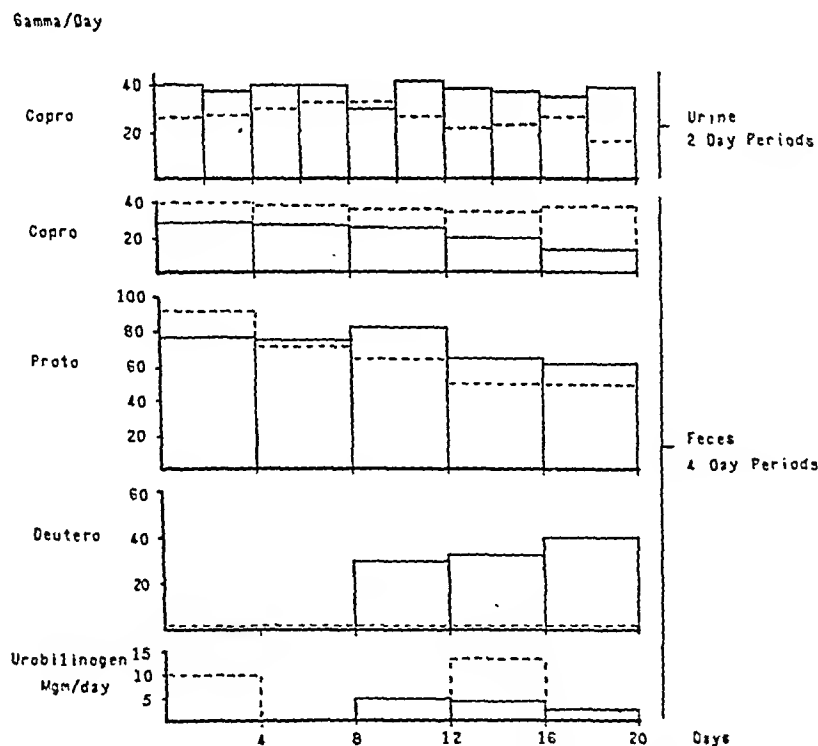

FIG. 1. NORMAL EXCRETION OF PORPHYRIN IN DOGS

Dog No. 1: Solid lines; diet—milk.

Dog No. 2: Broken lines; diet—"kibbled" dog food and milk.

MATERIAL AND METHODS

In view of the above considerations, the present study was planned as outlined in the following:

I. Studies on dogs.

A. *Feeding of blood*—two dogs.

B. *Feeding of raw meat*—two dogs.

II. Studies on human subjects.

A. *Cases having blood in the gastrointestinal tract due either to hemorrhage or to feeding of blood:*

Hemorrhagic gastritis, one case; malnutrition, one case; hepatic gumma, one case; bacterial endocarditis, one case; cholecystitis and cholelithiasis, three cases; infectious hepatitis (recovery phase), one case; carcinoma of head of pancreas, one case; cirrhosis and chronic alcoholism, two cases; idiopathic cirrhosis, one case.

B. *Feeding of crystalline coproporphyrins:*

1) Type III isomer—3–5 mgm. orally.

Bacterial endocarditis, one case; cholecystitis and cholelithiasis, one case; acute alcoholism, one case; active duodenal ulcer without hemorrhage, one case; cirrhosis and chronic alcoholism, one case.

2) Type I isomer—3 mgm. orally.

Cirrhosis and chronic alcoholism, one case.

The method used for determining coproporphyrin in the urine, both total and isomer distribution, was that of Schwartz and co-workers (33). The method for the feces was that described by Watson and Layne (34). This is not an exact procedure but permits a rough approximation of the three main types of porphyrins found in the feces: 1) coproporphyrin, 2) protoporphyrin, 3) deuterio- and the pseudo-deuterioporphyrins (19). The animals used were shepherd dogs, weighing 20–30 pounds, housed in standard metabolism cages which were so constructed that the urine could be collected quantitatively under a small amount of toluene preservative. During the control period, one dog was maintained on a strict milk diet, productive of marked constipation, the other on a diet of "kibbled dog food" and milk, with which the bowel movements were normal. The urine coproporphyrin determination was carried out every two days. As mentioned previously, coproporphyrin does not deteriorate significantly in this period of time. In the human experiments determinations were made on 24 hour samples of urine. The feces porphyrins in both dogs and humans were determined on four-day collections. Urobilinogen was determined by Watson's modification (35) of Terwen's method (36). Porphyrin isolations and melting point determinations were carried out according to previously described methods (19, 37, 38, 39). The total heme pigments of the feces were determined by the method of Flink and Watson (40). The crystalline

FIG. 2. EFFECT OF DIETARY CHANGE UPON THE PORPHYRIN EXCRETION Dog No. 1.

FIG. 3. EFFECT OF INGESTED BLOOD UPON THE PORPHYRIN EXCRETION IN DOGS
Dog No. 2; diet—"kibbled" dog food and milk.

coproporphyrins were fed as the hydrochlorides in a weakly acid solution. The diet was meat-free only in the cases indicated in Table I.

E. coli, *Acrobacter aerogenes*, *Pseudomonas aeruginosa*, and, in one instance, an inoculum of feces were utilized in studies of the *in vitro* synthesis of porphyrin by bacteria. The media employed were nutrient broth and tryptose broth, the same media with 5% citrated human blood added, and a synthetic medium of the Gladstone type. The periods of growth are indicated in Table II. The method of porphyrin extraction and separation in these experiments was similar to that used for the feces, save for the preliminary acetic ether extract of the liquid media. A spectrophotometric method was used in attempting to demonstrate heme pigments in plain broth (40).

RESULTS

Dog No. 1 (strict milk diet) excreted more urinary and less fecal coproporphyrin than dog No. 2 ("kibbled" dog food and milk) (Figure 1). On being changed from a milk diet to a diet of

"kibbled" dog food and milk, dog No. 1 showed a significant alteration in porphyrin excretion, *i.e.*, a decrease in urine and an increase in the feces. The total amount excreted, however, remained approximately the same (Figure 2). This interesting change will be considered subsequently. The porphyrin excretion by dogs No. 1 and No. 2 following the feeding of blood and of raw, red meat is shown in Figures 3 and 4. No significant increases in the UCP were observed after feeding blood (Figure 3).

Figure 4, which shows the effect of feeding washed, raw, red meat to dog No. 2, is also believed to be representative of experience gained in another similar study. At first glance, it might appear that the dog excreted increased amounts of urinary porphyrin following addition of meat to the diet. However, this increase was indeed slight and was maintained long after the meat was

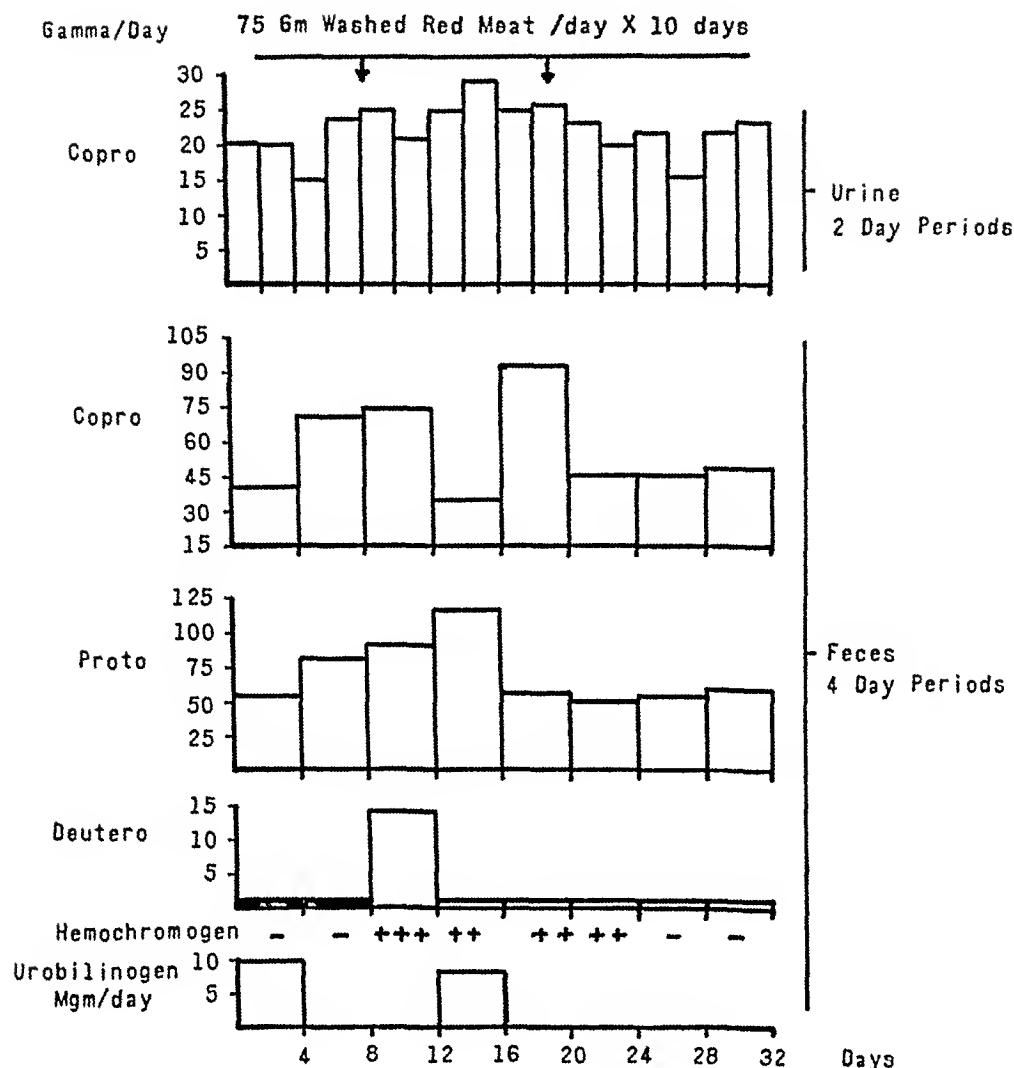

FIG. 4. EFFECT OF INGESTED RAW MEAT UPON THE PORPHYRIN EXCRETION IN DOGS
Dog No. 2; diet—"kibbled" dog food and milk.

discontinued; this may represent nothing more than a normal variation in excretion by the animal, a finding repeatedly demonstrated during the course of the dog experiments. Furthermore, the coproporphyrin methyl ester isolated from the urine during the control period and during meat feeding melted at 246°C . Since this is the type I isomer, it appears unlikely that any appreciable increase had been derived from the heme pigments of the fed meat. The findings in the feces of the two dogs following the feeding of both blood and raw meat, of which Figures 3 and 4 are representative, were quite similar. Increases in all three fractions were observed. The coproporphyrin of the feces after meat feeding was identified as the type I isomer in dog No. 2. The presence of small amounts of coproporphyrin III was strongly suggested by a highly colored mother

liquor following crystallization of the type I isomer, but further crystallization could not be effected.

Figures 5, 6, and 7 show the results of studies on several human subjects following the feeding of hemoglobin, coproporphyrin III, and in one instance, coproporphyrin I (Figure 5). Except where otherwise indicated, the studies were conducted in consecutive four-day periods. The results of studies on a 59 year old patient having outspoken evidence of cirrhosis and severe hepatic functional impairment associated with chronic alcoholism and dietary deficiency, are shown in Figure 5. Although the average excretion of urinary porphyrin is slightly greater after the feeding of hemoglobin, the occurrence of gross variations during the control period and in previous untabulated determinations, minimizes the significance of this increase. Moreover, the unexplained decrease

in the next four-day period, following the feeding of 5 mgm. of coproporphyrin III, is probably a further coincidental variation in excretion. The low values after 3 mgm. of coproporphyrin I were obtained during a later period, when the average urinary excretion was appreciably lower than that observed early in the patient's hospital course. Of principal importance is the fact that during both feeding experiments, approximately all of the fed coproporphyrin appeared in the feces and there was no increase in the urine. In one instance after the feeding of coproporphyrin III, the same isomer was easily crystallized and identified from the feces. Figure 6 shows the results of studies on a 62 year old woman with a high-grade biliary obstruction due to an impacted common duct stone. An increase in the urinary porphyrin excretion was observed on the third day following hemoglobin feeding, but during the corresponding four-day period, there was a diminished fecal coproporphyrin excretion, suggesting an increased ob-

struction to bile flow. There was no increase in urinary porphyrin excretion following the feeding of coproporphyrin III, most of which was accounted for in the feces. Further data on jaundiced subjects are shown in Figure 7: Case 12 (cirrhosis), Case 13 (calculus obstruction), and Case 14 (carcinomatous obstruction). The results of additional case studies are listed in Table I.

Case 2 (Table I) requires further explanation. This individual had taken alcohol rather continuously until the hour of admission in spite of epigastric pain and moderate hematemesis. The diet had been deficient for a matter of months prior to this time. The results of the study appear to indicate that significantly larger amounts of coproporphyrin were excreted in the urine while blood was present in the bowel. However, the "control" study, following cessation of bleeding, was conducted eight days later, when the patient was in a far better nutritional state and had not been drink-

FIG. 5. EFFECT OF THE INGESTION OF HEMOGLOBIN AND OF COPROPORPHYRIN III AND I UPON THE PORPHYRIN EXCRETION IN THE PRESENCE OF SEVERE LIVER DAMAGE

FIG. 6. EFFECT OF ORAL HEMOGLOBIN AND COPROPORPHYRIN III UPON THE PORPHYRIN EXCRETION IN HUMANS

ing. The effect of acute alcoholism upon the urinary porphyrin excretion is shown in Case 7, Table I, and will be discussed in detail in a subsequent paper of this series.

The results of studies of the synthesis of porphyrins by bacteria are shown in Table II.

DISCUSSION

The results of the studies on dogs maintained on different diets appear to permit either of two interpretations: (1) That the constipating effect of a milk diet promotes absorption of coproporphyrin from the bowel and consequent increase in urinary excretion; or (2) That the excretory function of the liver is relatively sluggish on a milk diet with the result that a larger fraction of the total appears in the urine. Since it would appear that a normal liver might be expected to handle the increment of coproporphyrin which an enterohepatic circulation due to constipation might conceivably

provide, we are inclined to favor the second of these two interpretations. It is quite possible that the bile flow is a major factor in the difference between the two diets; there is reason to believe that less bile would be formed on the milk diet alone because of its relatively higher carbohydrate, and lower protein content (3.5% as against 22.5%), and hence that less coproporphyrin might be excreted by the liver.

No conclusive evidence was obtained in the dogs of a process of reabsorption and increased excretion of coproporphyrin in the urine following the feeding of blood or meat. The increase of fecal coproporphyrin excretion observed in each animal in these experiments is probably related to an increased flow of bile, although a bacterial synthesis cannot be excluded. The finding that this increase is represented by the type I rather than the type III isomer favors the former rather than the latter possibility, since the coproporphyrin of

the bile has been shown to be type I, while the pre-existing evidence and that furnished by the present study indicate that bacteria elaborate type III.

The more detailed studies in human subjects also fail to furnish any conclusive evidence for a reabsorption of porphyrin from the bowel following the feeding of blood, regardless of the state of liver function. Moreover, the excretion of urinary porphyrin after the feeding of coproporphyrin III in five instances and of the type I isomer in one instance actually provides significant evidence to the contrary. Although these findings are at variance with those of Kaunitz and others after the feeding of hemoglobin or blood (3, 6) and coproporphyrin I (3), they are strongly supported in the present

investigation by the observation that the relative percentages of isomer types did not change. This finding practically excludes any appreciable contribution to the UCP of fed protoporphyrin type III (hemoglobin) or coproporphyrin III and I. Any increase in urinary coproporphyrin excretion following the feeding of either porphyrin would necessarily be of the same type. This assumption is based on chemical evidence that a transformation of one type of isomer to another would entail a disruption and complete resynthesis of the molecule. Although quantitative recoveries were seldom attained, it was obvious that the bulk of the fed porphyrin could be found in the following four-day collection of feces.

FIG. 7. EFFECT OF THE INGESTION OF HEMOGLOBIN UPON THE URINARY PORPHYRIN EXCRETION IN THE PRESENCE OF SEVERE LIVER DAMAGE (CASE 12) AND OF OBSTRUCTIVE JAUNDICE (CASES 13 AND 14)

Heme compounds not demonstrable in 200 cc. of plain broth after extraction and eight-fold concentration (40).

* An estimated half of the total porphyrin lost during extraction.

† Inoculated organism recovered in pure culture at end of experiment.

The increases in UCP observed in the cases of alcoholism included in the present study, are consistent with the usual finding in acute alcoholism of distinct increases of coproporphyrin III, sufficient as a rule to elevate the UCP value into the range of 120–500 γ /day. This will be considered in detail in a subsequent paper of this series. The regular increases in alcoholics not having blood in the intestinal tract, obviate the need of ascribing to such a source the increase observed in the cases of hemorrhagic (alcoholic) gastritis included in the present study.

Previous investigators (3, 6) have utilized a diet low in protoporphyrin content as a prerequisite to the demonstration of reabsorption of porphyrin from the bowel after the feeding of blood or porphyrin. Wherever it was feasible clinically, this plan was followed in the present investigation, in spite of which, the results in the studies on humans do not indicate any differences in urinary porphyrin excretion which might be attributed to the diet.

Just as in the dog experiments, increases of fecal coproporphyrin excretion were almost in-

variably observed following the feeding of blood to humans. One notable exception occurred in the case of high-grade biliary obstruction (Figure 6) which suggests that the elevations in the other instances were on the basis of increased flow of bile into the intestine. However, an alteration of the bacterial flora and consequently of bacterial synthesis of porphyrin, due to the exclusion of bile from the intestine, cannot be excluded. In this connection, it is of interest that preliminary studies have failed to reveal any effect of aureomycin, given orally, on the UCP. It is known that aureomycin markedly inhibits the bacterial flora of the colon, especially *E. coli*.

In the studies on bacteria, pure cultures of several organisms in broth media were found capable of synthesizing both coproporphyrin and protoporphyrin. In contrast to the results of previous studies (17, 18), relatively little protoporphyrin was recovered from the culture of *E. coli* in a medium containing blood. The explanation may lie in the much larger amount of hemoglobin which was exposed to bacterial action in the previous studies; it is also possible that the longer period of culture in the present study resulted in degradation and disappearance of an undetermined fraction of the protoporphyrin. The synthesis progressed despite the absence of demonstrable heme compounds, lending support to recent tracer studies which indicate that this process proceeds from simple precursor molecules such as acetate and glycine (41, 42).

SUMMARY AND CONCLUSIONS

1. Studies in dogs have shown that a milk diet is associated with a higher urinary and lower fecal coproporphyrin excretion than a diet composed of milk and prepared (kibbled) dog food. The total amount of coproporphyrin excreted is approximately the same, and the interpretation is favored that the hepatic coproporphyrin excretory function or the bile flow, or both, are relatively diminished on a milk diet.

2. No evidence was obtained either in dogs or humans, with normal or impaired liver function, of an absorption of coproporphyrin from the intestine and excretion in the urine, following the feeding of blood or raw meat, or spontaneous gastrointestinal hemorrhage. Increases were commonly encountered in the feces in such experi-

ments, but in instances where the porphyrin was identified it was shown to be the type I rather than the type III isomer.

3. No evidence was obtained in human experiments for the absorption from the intestine and excretion in the urine of fed coproporphyrin I or III. This was true in individuals with markedly impaired as well as normal liver function. The bulk of the fed porphyrin was recovered in the feces. Any small fractions that may have been absorbed were either metabolized or reexcreted in the bile.

4. A variety of bacterial strains, in pure culture, were found to synthesize both protoporphyrin 9 (type III) and coproporphyrin III. This synthesis did not proceed on artificial media of the Gladstone type, but required substances, presumably of protein character or origin, present in broth. The synthesis of porphyrins proceeded in broth media which did not contain demonstrable hemoglobin or heme pigments.

STUDIES OF COPROPORPHYRIN. III. IDIOPATHIC COPROPORPHYRINURIA; A HITHERTO UNRECOGNIZED FORM CHARACTERIZED BY LACK OF SYMPTOMS IN SPITE OF THE EXCRETION OF LARGE AMOUNTS OF COPROPORPHYRIN¹

By CECIL JAMES WATSON, SAMUEL SCHWARTZ, WILLIAM SCHULZE,
LEON O. JACOBSON, AND RALPH ZAGARIA

(From the Department of Medicine, University of Minnesota Hospital, Minneapolis, and the
Metallurgical Laboratory of the University of Chicago [now the
Argonne National Laboratory])

(Received for publication July 9, 1948)

It has been generally assumed that the formation and excretion of large amounts of coproporphyrin is regularly associated with the presence of symptoms, usually of either abdominal or nervous type. Certain students of the porphyrins, notably Carrié (1) have ascribed to coproporphyrin a primary rôle in the symptoms of lead poisoning and other conditions associated with a considerable increase of coproporphyrin excretion. Thus, the abdominal pain and peripheral neuritis are designated by Carrié as "porphyrinopathic" manifestations. Intermittent acute porphyria, characterized by production and excretion of the wholly abnormal Waldenström uro-type porphyrin, is often entirely latent and symptomless for long periods, probably, even, for the individual's entire life span in some instances. So far as can be determined, however, no case has been recorded in which there was a massive and persistent, and at the same time entirely symptomless idiopathic coproporphyrinuria. At least until further knowledge may indicate a different terminology, it is believed best to use this designation, rather than porphyria, for the cases which will be described. In agreement with Waldenström, we prefer to reserve the latter term for cases in which uroporphyrin, or porphyrins of uroporphyrin type, such as the Waldenström or 260 porphyrin (2-4), are demonstrated. The term porphyria, in other words, connotes a metabolic error in which an entirely abnormal porphyrin is formed and excreted, while the term coproporphyrinuria is non-committal in the sense that while it is both physio-

logical and pathological, secondary to a variety of disturbances, the possibility exists that occasional cases, such as those described in the following, are likewise "inborn errors of metabolism."

CASE REPORTS

Case 1. W. V. Q., ♂, 26, white, chemist. This individual had no complaints and considered himself to be in excellent health.

As a graduate student he had worked for one and a half years in a laboratory in which 1-2 pounds of mercury were always kept in an open vessel. He recalls "one or two" mercury spills in the course of his own work, in which he wiped up the mercury with copper powder. Once, during this same period, about two years prior to the present study, he was pipetting mercury and some entered his mouth, but he is certain that none of it was swallowed. Also about two years ago while pipetting saturated copper sulphate solution, some got into his mouth. He thought none was swallowed but he noted a "funny" feeling in the stomach for several hours. In addition to these episodes he has been exposed only to the usual organic and inorganic compounds found in most chemical laboratories. So far as could be determined alcoholic beverages were but rarely used and only in small amount.

As a child he had had measles, mumps and chicken pox, and pneumonia at 11. His mother died of tuberculosis at 56, his father is living and well, as are three siblings. Neither the patient nor members of his family have ever noted red urine, and none have had suggestive complaints such as abdominal pain, severe constipation, or pain in the extremities. There has been nothing suggestive of light sensitivity in the patient or his relatives.

The physical, including the neurological examination was entirely normal. The blood pressure was 120/70. The routine examinations of the blood and urine were normal. There was no anemia. The blood smears revealed nothing abnormal; there was no increase in basophilic stippling. The sternal bone marrow was normal. The feces urobilinogen for three separate four-day periods was 83, 86, and 118 mgm./day; thus there was no evidence of an increase in rate of blood destruction, in fact,

¹ Aided by grants from the John and Mary R. Markle Foundation, the Rockefeller Foundation, and the Medical Research Fund of the Graduate School, University of Minnesota.

the values are rather low. There was no evidence of liver functional impairment. Thus the urine urobilinogen on three occasions was well within normal limits, 0.05, 0.06, and 0.12 mgm./100 cc. The cephalin-cholesterol flocculation test was negative. Repeated serum bilirubin determinations were well within normal limits. The urine coproporphyrin was greatly increased as noted in Table I.

TABLE I

Urine coproporphyrin—case W. V. Q. and siblings

Case W. V. Q.	Date	Concentration in $\gamma/100$ cc.
	4-24-45	218.0
	5-1-45	142.0
	5-22-45	96.5
	6-8-45	126.3
	6-16-45	255.0
	7-20-45	108.0
	9-18-45	381.5
	12-18-45	201.0
	1-23-46	449.0
Sister M.	7-11-45	2.9
	7-28-45	4.6
Brother Ro.	7-11-45	3.3
Brother Ru.	9-20-45	4.1

The urine was examined repeatedly for the presence of ether insoluble porphyrins, such as uroporphyrin or the Waldenström porphyrin, but none were demonstrable. The test for porphobilinogen (5) was made on a number of occasions and with one exception was negative. The exception was a very faintly positive reaction of doubtful significance.

The isomer distribution of the UCP was determined on two occasions with the following result:

11-16-45	86% type III
	{ 91% type III
12-28-45	{ 95% type III

The first two of the above results were obtained with the B modification of the isomer analysis method, the third with the A procedure (6a). As noted in paper I of this series (7), the results of these two techniques are essentially the same.

A spectrographic metal analysis² of the urine of W. V. Q. did not reveal any abnormal amounts of metals.

²Carried out by the spectrochemical division of the Metallurgy Laboratory University of Chicago, to whom we are indebted for the report.

TABLE II

Fecal porphyrin concentration in case W. V. Q.

Date	Coproporphyrin $\gamma/100$ Gm.	Protoporphyrin $\gamma/100$ Gm.*	Deuteroporphyrin $\gamma/100$ Gm.*
6-8-45	69000	1263	—
9-21-45	32375	381	638

* The values for proto- and deuteroporphyrins are given in coproporphyrin equivalents.

The fecal porphyrins were quantitated on two occasions with results as given in Table II.

On several occasions the isomer distribution in the urine was determined by means of the differential precipitation method (6a). From 86-95% coproporphyrin III was found. Coproporphyrin III methyl ester was repeatedly isolated in considerable amount from both feces and urine. The crystal habitus and dimorphic melting point were characteristic (8). The methods of isolation have been described elsewhere (4, 8, 9).

Gastric and duodenal contents were examined, with the results shown in Table III.

The erythrocyte protoporphyrin was determined on two occasions by the method of Grinstein and Watson (10).

9-29-45	46 $\gamma/100$ cc. of cells
3-24-46	37 $\gamma/100$ cc. of cells

On neither occasion was there any demonstrable coproporphyrin in either erythrocytes or plasma.

Examination of the bone marrow revealed a normal morphology. The protoporphyrin concentration was 37 $\gamma/100$ cc. No coproporphyrin was demonstrable.

Case 2. B. C., ♂, 31, negro laborer. Admitted to the Minneapolis General Hospital on January 23, 1948, with a diagnosis of diphtheria. A typical membrane was observed in the pharynx and throat cultures were positive for *B. diphtheriae*. The illness was not severe and there were no recognizable complications. 40,000 units of anti-toxin were given on the day of admission. The patient made an uneventful recovery. The highest temperature recorded was 102° F., on the day of admission. The temperature was consistently normal after the second hospital day.

TABLE III

Coproporphyrin concentration in gastric and duodenal contents

* 95% copro-III according to differential precipitation technique (6a).

The urinary coproporphyrin was studied in this case because of the previous observations that diphtheria bacilli in broth cultures produce coproporphyrin in considerable amount (11). This has recently been shown to be the type III isomer (12). The present case was one of a group of diphtheria cases under investigation with respect to possible increases in UCP. It was surprising to find that this individual was excreting unusually large amounts of coproporphyrin, and that this greatly heightened excretion persisted long after the diphtheria had disappeared. There were no symptoms other than those related to the throat, of transitory nature. There was no history of exposure to chemicals or heavy metals, and the patient denied the use of alcoholic beverages in any form. There was no evidence of liver functional impairment. Thus the serum bilirubin was: 0.2 mgm./100 cc. (1' or prompt direct) and 0.9 mgm./100 cc. total; the cephalin cholesterol test was negative and the thymol turbidity 1.9 units; the serum alkaline phosphatase was 4.0 Bodansky units.

The patient was uncooperative and, although attempts were made to keep him under observation indefinitely, he left Minneapolis toward the end of April for an unknown destination.

The findings in this case were as follows:

TABLE IV
Urinary porphyrin excretion

Date	UCP	% type III isomer	M.P. of cryst. methyl ester	Porphobilinogen reaction (5)	Uroporphyrin
	$\gamma/24$ hrs.		$^{\circ}$ C.		
1-25-48	8,674	99	130-1	negative	0
1-30-48	3,980	100		negative	0
2- 5-48	2,000			negative	0
2- 7-48	1,890				
2- 8-48	1,610	98		negative	0
2-14-48	1,465			negative	0
2-16-48	3,062	98			
2-19-48	4,260				
2-20-48	3,780				
2-24-48	5,150	100	130-1	negative	0
2-25-48	6,468			negative	
2-27-48	4,959				
3- 3-48	6,177	99	130	negative	0
3- 6-48	4,940				0
4-20-48	206 γ % (vol. unknown)				

Bile containing duodenal contents were obtained on 2-8-48. These exhibited intense red fluorescence and were found to have a coproporphyrin concentration of 128 γ /100 cc. of which 82% was the type III isomer.

The erythrocyte protoporphyrin on 2-10-48 was 36 γ /100 cc. of cells. No porphyrin could be demonstrated in the plasma.

DISCUSSION

The two cases which have been described are of a type hitherto unrecognized. They are important

TABLE V
Feces porphyrin findings

Date	Copro-porphyrin	% type III isomer	M.P. of cryst. methyl ester	Uroporphyrin
	$\gamma/100$ Gm.		$^{\circ}$ C.	
2-10-48	32,800	90	—	0
2-15-48	39,600	90	130-1 $^{\circ}$	0
2-16-48	40,200	—	—	0

from a number of standpoints, one of which was referred to in paper I of this series (7), which dealt with the normal coproporphyrin of the urine. It is evident that if an individual such as one of the two present cases contributed to a pool being collected from presumably normal individuals, as in Grotepass' study (13), the result would be affected to a very marked degree and would be interpreted erroneously. The complete lack of symptoms in these two individuals is of much interest since it casts considerable doubt on the belief that the symptoms of lead poisoning and porphyria are "porphyrinopathic," as Carrié and others have believed. In porphyria, of course, compounds other than coproporphyrin III may well be implicated, but in lead poisoning one finds only coproporphyrin III. It appears, however, that there is one striking difference between the present cases and cases of lead poisoning, in so far as porphyrin excretion is concerned. But slight or no increases of coproporphyrin III are encountered in the feces in lead poisoning³ even though relatively large amounts are present in the urine. In the present cases the amounts in the urine were considerably larger than those usually encountered in lead or other heavy metal poisoning, while the fecal coproporphyrin III was roughly ten times that of the urine. Thus it is evident that the total production of coproporphyrin in these two individuals is on a much larger scale than that of the secondary coproporphyrinurias of ordinary type. This would support the belief that the disturbance in the present cases represents an "inborn error of metabolism," albeit one that differs fundamentally from that of ordinary porphyria, in which uroporphyrin or uro-type porphyrins are also found.

In Table V it is noted that 90% of the fecal coproporphyrin was type III. This would indicate that 10%, or from 3280-4020 γ /100 Gm., was

³ At least in chronic cases. We have not had opportunity to study the fecal coproporphyrin in cases of acute plumbism.

type I. This value would exceed the normal by approximately ten-fold. In the crystallization of the methyl ester, no evidence was observed for such an amount of copro-I as this figure would indicate. The isomer percentage values cannot be regarded as absolute, simply providing an approximation of the relative amounts of the two isomers. This is particularly true when either isomer constitutes more than 85% of the mixture (6b). If the value had been 98–99% type III, as in the case of the urine, a normal amount of type I isomer would have been indicated. As it is, a moderate increase cannot be excluded.

SUMMARY AND CONCLUSIONS

1. Two cases are described in which a great increase of coproporphyrin III excretion was unaccompanied by symptoms or signs of porphyria, metal or chemical poisoning or liver disease. The first case was that of a chemist who had had exposure to heavy metals and chemicals, of doubtful significance. The second was a negro laborer who suffered from mild diphtheria at the outset of the study, but whose heightened porphyrin excretion persisted for months after the diphtheria had disappeared.

2. Careful studies of several members of the family of the first case yielded no evidence of any disturbance of porphyrin metabolism. In the second case no other members of the family were available for study.

3. The duodenal contents in each instance contained large amounts of coproporphyrin III, presumably contributed by the bile. The feces contained corresponding increases, ranging from 32 to 69 mgm./100 Gm., from 10 to 20 times the amount in the urine. It is emphasized that this is quite unlike the ratio in chronic lead poisoning, in which considerably more coproporphyrin III is found in urine than in feces.

4. In neither case did the urine contain porphobilinogen or uro-type porphyrins.

5. The blood serum or plasma in the two instances was free of demonstrable porphyrin. The erythrocyte protoporphyrin was not significantly elevated in either case.

6. The general significance and probable constitutional nature of these cases is discussed.

INTRA-ARTICULAR TEMPERATURE AS A MEASURE OF JOINT REACTION

By STEVEN M. HORVATH AND JOSEPH L. HOLLANDER¹

(From the Department of Physical Medicine and the Arthritis Section of the Hospital of the University of Pennsylvania, Philadelphia)

(Received for publication September 8, 1948)

Clinicians studying Rheumatic Diseases have long used the surface temperature over the joints as indicative of the degree of synovial reaction. Many of the terms used in rheumatology imply temperature changes in the joint tissues, viz. "the acute hot joint of gout," "the cold swelling of chronic rheumatoid arthritis," the so-called "friction effect" or "heating-up" of osteoarthritic joints following exercise, or "articular jelling" (implying excessive joint cooling and stiffening on prolonged rest). Many measurements have been made of the skin temperature over diseased joints, but no study on intra-articular temperatures in human joints has been reported. Several studies (1-4) have been made of intra-articular temperatures in dogs and one study (5) was performed on the stifle joint of a horse to determine the coefficient of friction within the joint, with and without synovial fluid.

METHOD

In an effort to find a method for more accurate evaluation of activity of joint disease, and for determination of the effects of rest, exercise, physical therapy, drugs, and Roentgen rays on joints, the following technique for determining intra-articular temperature has been developed.

Temperature studies were performed on the joints of normal volunteers and arthritic patients. All the studies were carried out in a room having a mean temperature of 24° C. The subjects were reclining quietly for at least one half hour prior to the studies. Because of the ease of approach, the knee joint was the usual site of study. The skin was sterilized with an antiseptic (merthiolate) solution. The skin and joint capsule at a point one half inch medial to the medial border of the patella and high enough to avoid the fat pad was infiltrated with several cubic centimeters of 1% procaine solution. A 19 gauge needle was inserted through the synovial membrane into the joint space under the patella. Even in most normal joints, a few drops of fluid could be aspirated into a dry syringe. When it was certain that the point of the needle was under the patella and in the joint space, the

syringe was removed and a fine copper constantan thermocouple or a thermistor was threaded through the needle to a depth of several inches in order to project freely into the joint space. The needle then was either left in place or, more frequently, removed leaving the temperature-sensitive element in place. The emf developed by the thermocouples was measured by a Leeds and Northrup type K potentiometer, and the change in resistance of the thermistor was measured with a Wheatstone bridge. Thermocouples or thermistors were also fixed on the skin over-lying the patella, and in most cases a thermocouple was also placed on the skin of the opposite knee. Control temperature readings were taken after the joint had been at rest, with the element in place, for at least one half hour. If a therapeutic procedure was employed to modify joint temperature which would not permit leaving the metal thermocouple in place, it was removed. Immediately after the treatment, another aspiration and insertion was made at the same site in order to determine the magnitude of the elevation and to obtain a measure of the rate of cooling.

RESULTS

The amount of synovial fluid present appeared to make little difference in the joint temperature except to alter the rate of change. The position of the temperature-sensitive element in the joint was relatively unimportant. The thermocouple or thermistor often was inserted a distance of three or more inches into the joint space. Temperature measurements made during withdrawal of the element showed no appreciable variation until the measuring element was out of the joint. Thirty-one determinations of the internal temperature of the knee joint and the over-lying skin surface have been obtained on 25 individuals. Two studies were made of the elbow joint in one patient. In no instance was the rectal temperature elevated at the time of study. Four subjects were essentially normal except for possible age changes (all were between 35 and 42 years). Twelve patients had rheumatoid arthritis. Seven had degenerative joint disease; one had Reiter's syndrome and one had gouty arthritis. The degree of local clinical

				Slight	89.4	87.4
13	Chronic Gout	36	M	Moderate	96.0	89.2
					96.1	90.0

activity in the joint tested was estimated by the presence and severity of the following: swelling, tenderness, effusion and limitation of motion by pain.

The values obtained are presented in Tables I and II. The correlation ($r = 0.65$) of joint temperature with surface temperature was generally good, but there were notable exceptions. In one patient the joint temperature was as much as 7.6° F. higher than the skin temperature, while in two others the surface temperature was higher than the intra-articular temperature. Relatively few normal joints have as yet been studied to determine the variations in resting temperatures. The difficulty of obtaining volunteers has somewhat hampered this evaluation. However, skin temperatures thus far obtained in "normal" subjects range from 85.2° F. to 89.5° F. and joint temperatures from 88.6° F. to 91.1° F.

In degenerative joint disease clinical activity was difficult to evaluate. Patients with this disease had, in most cases, normal skin temperatures but their joint temperatures were all moderately elevated. In the cases of chronic gout and Reiter's syndrome the skin temperatures were normal although joint temperatures were definitely elevated.¹ The clinical improvement in the patient

¹ A knee joint temperature of 98.6° F. was observed recently in a patient in an active stage of gout.

with Reiter's syndrome was reflected in the lowered joint temperatures. In rheumatoid arthritis the highest joint temperature, 97.1° F., was recorded in an elbow joint. The highest surface temperature was 95° F. In case No. 25 where the rheumatoid process was completely quiescent, both the skin and joint temperatures were subnormal. In rheumatoid arthritis there was a positive correlation of both surface and joint temperature with relative clinical activity (Figure 1). The correlation appears to be somewhat better with joint rather than with surface temperature. In one individual the surface temperature was higher than the joint (Table II).

A variety of physical measures were employed to modify the joint temperature. Although results will be reported in detail in a subsequent paper (6), some observations of interest, primarily in reference to the joint reaction itself, are reported herein. Fever therapy, induced by a pyrogen injected intravenously, resulted in increased joint and sur-

face temperatures. When rectal temperature was elevated to 103° F., a joint temperature of 101° F. (an increase of 5.2° F.) and a skin temperature of 99.4° F. (an increase of 8.3° F.) was noted.

On another occasion, with a rectal temperature of 105.2° F. a joint temperature of 97.1° F. was obtained, but at this time the patient was being cooled by application of ice bags to the thighs. Even under these circumstances, the knee joint temperature was elevated 2° F. over the control observation.

Observations were made on the influence of hot and cold packs on both normal and inflamed joints. The application of *hot* packs invariably resulted in a depression of the intra-articular temperature of as much as 2.2° F. Continued reapplication of these hot packs produced steadily diminishing effects, although even after the tenth hot pack of a series, the joint temperature was still definitely lowered. The internal temperature quickly returned to control levels after discontinuation of the packs and five to ten minutes later the values were slightly higher, a positive reflex effect (Figure 2). Cold packs, on the other hand, raised joint temperatures appreciably. Hot or cold packs applied to one knee produced reflex effects in the opposite knee of similar character. These studies were performed in the winter months. When observations were resumed during the summer, it was surpris-

FIG. 2. REFLEX PHENOMENA ASSOCIATED WITH THE APPLICATION OF HOT AND COLD PACKS OVER THE JOINT

All points indicate joint temperatures. The dotted lines indicate the shift of the temperature from control values during the first minute of pack application.

TABLE III

Seasonal influence on the temperature reaction of the knee joint to hot or cold wet compresses. Maximum changes occurred within the first two of the five minutes during which the packs were applied

	Exp.	Type of pack	Maximum change, ° F.	
			Knee joint	Surface
Winter	1	Hot (108° F.)	-2.3	12.2
	2	Hot	-0.8	5.1
	3	Cold (65° F.)	2.5	-9.1
	4	Cold	5.0	-10.1
	5	Cold	2.6	-6.1
Summer	6	Hot	-0.4	6.4
	7	Hot	-0.5	5.8
	8	Hot	-0.5	5.1
	9	Hot	0.2	7.5
	10	Cold	0.5	-3.6
	11	Cold	0.4	-8.1

ing to note that although the pattern of the reflex was similar, the magnitude of the response was diminished (Figure 2 and Table III). This difference seems to be related to the relative degree of vascular tone exhibited by individuals at the various seasons of the year (7, 8).

Painful stimuli, apprehension, alarm or smoking lowered the skin and elevated the joint temperature in all cases so studied. Simple passive and non-weight-bearing active movement of the joint was performed in several instances. Temperature increases of as much as 2.5° F. were noted. The joint temperature following periods of active exercise showed varying degrees of elevation with rapid cooling on rest.

DISCUSSION

These preliminary observations of joint tissue temperatures in some of the forms of arthritis appear to indicate that an accurate evaluation of the degree of inflammation in a joint may be obtained by this method. A close correlation between the internal joint temperature and the clinical evaluation of activity of disease was not surprising and indicated that the temperature of the synovial fluid was directly dependent on the relative hyperemia of the synovium. However, the data would indicate that it is extremely difficult to evaluate the lower degree of clinical activity. The amount of heat "felt" externally over a joint was usually, but not necessarily, related to joint temperature. In degenerative joint disease, the elevation of joint

temperature noted seemed more closely correlated to the apprehension of the patient and the amount of adipose tissue about the knee than to the clinical activity as determined by external examination. The slow drop seen with continued rest in these patients would imply that this elevated temperature was real and was related to increased friction effect and retarded cooling.

Incidental observations were made on pain sensitivity of the synovium and cartilage, confirming the observations of Smyth and Freyberg (9, 10). The synovium was quite tender whenever touched at any point that had not been anesthetized with procaine. If the thermocouple was inserted far enough to touch the synovium on the opposite side of the patella, a sharp pain was produced. The articular cartilage, however, seemed entirely insensitive when touched, or even when accidentally penetrated by the aspirating needle or tip of the thermocouple.

In conjunction with the studies on the effectiveness of physical therapy procedures (6), one particularly interesting phenomenon was observed. Application of hot packs increased surface temperature markedly, but decreased the deep. A secondary rise of joint temperature occurred following removal of the packs. Cold packs to the knee surface, however, produced a definite cooling of the skin and a lasting increase in joint temperature. The intensity of hot and cold applications was not sufficient to induce pain in most instances but apparently this phenomenon is a sympathetic reflex effect associated with the principle of counter-irritation. The magnitude of this effect is apparently related to the state of vascular tone and dependent upon the season of year that observations were made (7, 8).

It appears significant that cold, pain, fear and smoking produced identical effects (*i.e.*, lowering of the skin and elevation of the joint temperatures). Perhaps this observation may lead to an explanation of how such factors aggravate the symptoms of an arthritic process. The effects of vaso-dilating and vaso-constricting drugs, deep X-ray therapy, exercise and other agents on the synovial circulation are being studied by this method. Finer measuring units have been developed which will make it possible to study temperatures in fingers, wrists, and other small joints.

No ill effects from these studies were noted in any of the patients. One study on a normal volunteer resulted in a slight synovitis of two days' duration, after weight-bearing exercise with the thermistor in place. Many of our patients expressed improvement after this "treatment," showing the psychic benefit derived from any robust procedure and the special interest exhibited by the physician.

SUMMARY

1. A method for the determination of the temperature of the articular cavity has been developed which appears to have a practical use both to measure the degree of inflammation in the joint and to determine the effect of external influences on joints.

2. Intra-articular temperatures correlated somewhat more closely than the surface temperatures over the joint with the clinical activity of rheumatoid arthritis.

3. The joint temperatures in degenerative joint disease were higher than anticipated from relative clinical activity. This might be related to greater joint friction effects and to retarded cooling.

4. The joint temperature fell when hot packs were applied over the joint, and rose with the application of cold packs. The magnitude of these

responses was affected by seasonal influences being greater in the winter than the summer.

III. THE FATE OF CITRATE IN ERYTHROBLASTOTIC INFANTS TREATED WITH EXCHANGE TRANSFUSION^{1, 2}

By IRVING B. WEXLER, JOSEPH B. PINCUS, SAMUEL NATELSON,
AND JULIUS K. LUGOVOY

(From the Department of Pediatrics and the Department of Biochemistry,
The Jewish Hospital of Brooklyn, Brooklyn, New York)

(Received for publication September 15, 1948)

Since the adoption of exchange transfusion as a method in the treatment of newborn infants with severe erythroblastosis (1-3) the question of the possible toxic effects of sodium citrate added to the administered blood, to prevent coagulation, has arisen (4). In this procedure from 85 to 95% of the infant's Rh-positive erythrocytes are replaced by the donor's Rh-negative erythrocytes depending upon the volume of blood that is administered and simultaneously removed (5). In order to effectuate an exchange of 85%, a quantity of blood equivalent to twice the infant's blood volume must be used, and for an exchange of 98%, a quantity of blood equivalent to four times the blood volume must be used. Since the average newborn infant has a blood volume in the range of 250-300 ml. the procedure involves the use of approximately 500 ml. and approximately 1,000 ml., respectively. With the use of sodium citrate as an anticoagulant the infant receives as much as 60 to 120 ml. of a 3% solution of sodium citrate intravenously over a period of about 1½ hours.

In the experimental animal, the intravenous administration of large quantities of sodium citrate has been shown to produce convulsions (6). This has been ascribed to the formation of a poorly ionized calcium citrate complex which removes calcium ion from the blood stream (7-9). Despite this consideration, exchange transfusions have been successfully carried out in a large number of cases, although occasionally deaths have been reported in the very severely affected cases (10).

In order to study the adjustment that the newborn makes to the physiological strains to which it is subjected when an exchange transfusion is

carried out, citric acid, calcium, phosphorus, protein and total base levels were studied before, during and after such a transfusion on a newborn with no symptoms of erythroblastosis and with apparent normal hepatic and kidney function. The newborn studied was a mongolian idiot born in normal delivery. In addition citric acid determinations were carried out on serial bloods withdrawn from eight erythroblastotic infants during exchange transfusion.

500 ml. of blood were freshly drawn from a compatible donor. To this were added 60 ml. of 3% sodium citrate (dihydrate of tri-sodium citrate). This made a total volume of 560 ml. Over a period of approximately 60 minutes 500 ml. of this citrated blood were infused into the saphenous vein at the ankle. After 60 ml. had been infused the radial artery was cut and the blood was collected in 60 ml. portions, during the progress of the transfusion. The first 60 ml. were added without removal of blood in order to dilate the blood vessels and make the radial artery more apparent. The cells were separated by centrifuging and the plasma was analyzed for the various blood constituents.

Citrate determinations were carried out by a method previously described (11, 12). Calcium was done by direct precipitation from plasma (13) without ashing. Where citrate was at a high level the results were later shown to be significantly low because of the interference of citrate with calcium precipitation. The determinations could not be repeated with ashing subsequently because calcium salts were found precipitated in the plasma on standing. The calcium results were discarded and are not reported except where the citrate levels were low enough so as not to interfere, or where analysis was done by ashing on plasma from freshly drawn blood. Phosphorus was determined colorimetrically (14), total protein by a modified biuret method (15) and total base by electrodialysis (16).

The results obtained on the blood of the donor with added citrate, and on that of the newborn with no symptoms of erythroblastosis are shown before and after the transfusion in Table I. The results are averages of duplicates. Standards and recovery of added amounts of the constituents

TABLE I

Comparison of citrated adult blood plasma with that of the blood plasma of the infant before and after the exchange transfusion

Sample	Phosphorus	Total base	Total protein	Calcium	Citric acid
	mg. %	meq./l.	%	mg. %	mg. %
Citrated Adult Plasma	3.7	178	6.7	9.8*	340 †
Infant's Pre-Transfusion	7.2	150	5.14	10.8	2.9
Infant's Post-Transfusion (one hour)	6.4	148	5.48	10.0	6.69
Infant's Post-Transfusion (19 hrs.)	—	—	4.6	10.3	1.47

* Determination on ashed plasma.

† Assuming a 40% hematocrit and no citric acid in the red cells the total citric acid added in 500 ml. of whole citrated blood would be: $5 \times 340 \times 0.6 = 1,020$ mg.

were also run. The results are in error by less than 5%. Calculations in the table assume no citrate in the red cells. Previous work indicates that in normal blood no significant amount of citric acid is found in the red cell (11).

Analysis for citric acid, phosphorus, protein and total base of the 60 ml. portions of the blood removed from the infant during the transfusion is shown in Table II. These determinations were done on plasma.

A chart showing the changing citric acid levels with time, for the infant with no symptoms of erythroblastosis, is plotted in Figure 1.

TABLE II

Analysis for citric acid, phosphorus, total base and protein on the plasma of the blood removed in 60 ml. portions during a 500 ml. exchange transfusion

Seven portions removed for a total of 420 ml.

Plasma sample (in order of removal)	Phosphorus	Total base	Total protein	Citric acid	Total citric acid removed in each 60 ml. sample of whole blood*
	mg. %	meq./l.	%	mg. %	mg.
1	7.5	—	—	12.3	4.4
2	7.6	—	5.21	25.4	9.2
3	6.8	—	—	19.0	6.4

FIG. 1. CITRIC ACID LEVELS DURING AN EXCHANGE TRANSFUSION WITH CITRATED BLOOD ON A MONGOLOID INFANT WITH NO SYMPTOMS OF ERYTHROBLASTOSIS OR OF LIVER OR KIDNEY DAMAGE

In the eight cases of newborns with symptoms of erythroblastosis the determinations had to be limited to blood obtained during the transfusion. With the exception of Cases 2 and 6 the first sample obtained followed the administration of about 50–60 ml. of donor's blood and thus already contained added citrate. During the course of the transfusion, whenever symptoms of tetany or convulsions were impending or apparent, 5 ml. of a 10% solution of calcium gluconate were injected intravenously. In some instances, calcium gluconate was administered at various points in the procedure whether symptoms were or were not present.

The results obtained in six of these cases are shown in Figure 2. The scales of the graphs for Cases 3 and 4 are different with respect to citrate administered from that for Cases 5–8. In the first two cases 500 ml. of blood were infused, in the last four 1000 ml. of blood were used. Points at which calcium gluconate was administered are indicated with an arrow. These infants survived and have been followed for a period of at least six months and are all well. The details of their clinical course are incorporated in another report (17).

One infant in this series died within 24 hours after the transfusion. The changing citric acid levels for this infant are shown in Figure 3. On postmortem examination the liver of this child showed severe necrosis.

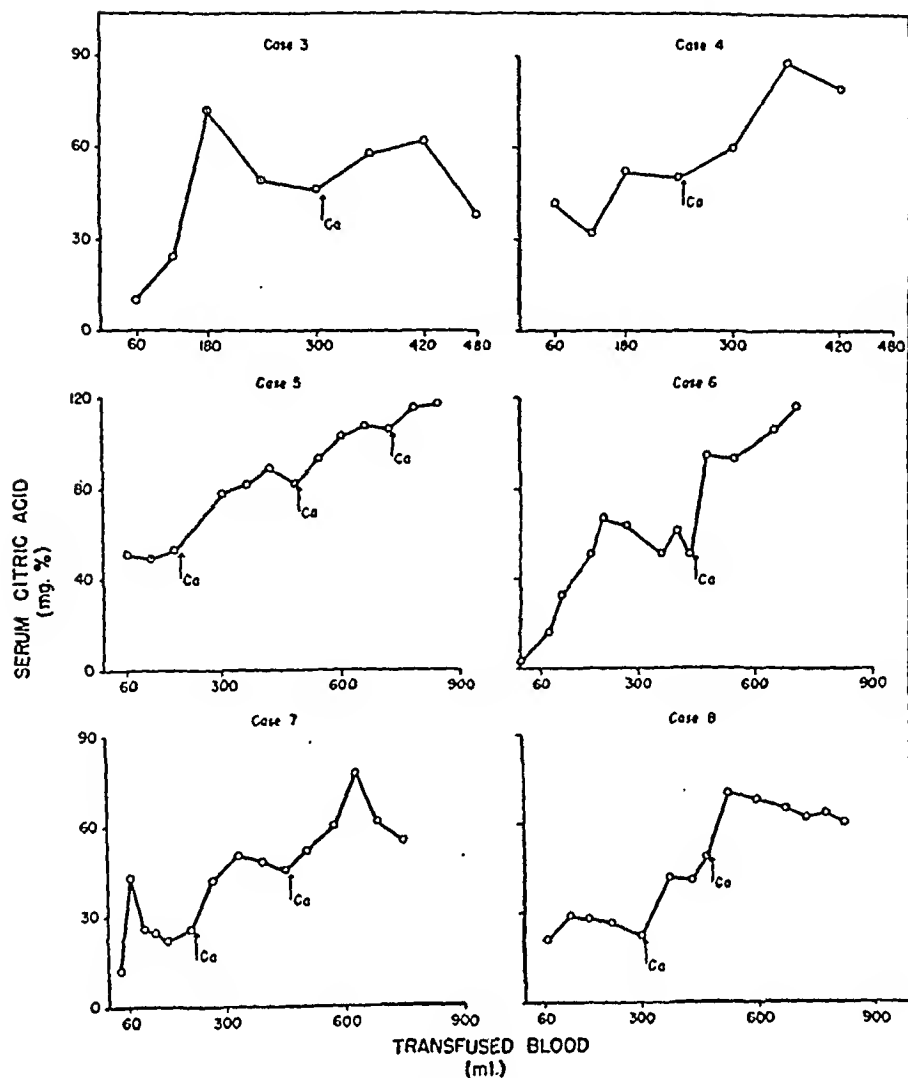

FIG. 2. CITRIC ACID LEVELS ON SIX ERYTHROBLASTOTIC INFANTS TREATED WITH EXCHANGE TRANSFUSIONS WITH CITRATED BLOOD. EFFECT OF ADMINISTRATION OF CALCIUM ON THE CITRATE LEVEL

Arrows indicate time of injection of calcium gluconate.

In view of the fact that we were unable to obtain the true total calcium values on the plasma of the infant with no symptoms of erythroblastosis fetalis, we studied the changing calcium values in a child with erythroblastosis fetalis during treatment with exchange transfusions. The bloods were dried at 100° C. and ashed in a muffle furnace at 475° C. before analysis so as to remove citrate interference. The results are shown in Figure 4 and Table III.

DISCUSSION

Examination of Tables I and II indicates a remarkable ability of the infant with no apparent liver or kidney damage to remove citric acid from the blood stream rapidly. After the addition of 60 ml. of citrated blood the citric acid level in the

plasma of the infant should rise, according to calculations, to approximately 60 mg.%.³ Actually, after the adding of the first 60 ml. of citrated blood, the level rises to 10 mg.%. In this infant the citric acid level never rose above 40 mg.% while

³ This figure is arrived at by assuming a 275 ml. blood volume and a hematocrit which is the same in the administered and endogenous blood. With a 40% hematocrit the infant's plasma volume would be 165 ml. For a 3 mg.% citric acid level in the plasma the total citric acid in this plasma would be 5 mg. Sixty ml. of citrated blood would contain 36 ml. of plasma with a citric acid concentration of 340 mg.% as determined. The citric acid content of this plasma would be 122.5 mg.%. The total citric acid in the combined volume of blood plasma (165 + 36 = 201 ml.) would then be 122.5 + 5 = 127.5 mg. Expressed in mg.% this would be 127.5/2.01 = 63.5 mg.%.

FIG. 3. CITRIC ACID LEVELS DURING AN EXCHANGE TRANSFUSION ON AN ERYTHROBLASTOTIC INFANT WHO DID NOT SURVIVE FOR MORE THAN 48 HOURS AFTER THE TRANSFUSION

Arrows indicate time of calcium gluconate injection.

TABLE III

* After 5 ml. of 10% calcium gluconate were added.

† Determined on ashed plasma.

the blood infused contained a concentration of 340 mg.%. According to the equation derived by Wiener (5), at the end of a 500-ml. transfusion 85% of the infant's blood has been replaced by the blood of the donor. At the end of a 1000 ml. transfusion 98% of the infant's blood has been replaced. As early as one hour after the termination of the procedure the level had dropped to almost the fasting level. The fasting level for newborn is of the order of 2-3 mg.% as reported previously (18, 19). A sample taken 19 hours later showed a level within the normal range.

In the last column of Table II are listed the actual quantities of citric acid that were removed from the infants at intervals during the procedure.

FIG. 4. CITRIC ACID AND TOTAL CALCIUM LEVELS DURING AN EXCHANGE TRANSFUSION ON AN ERYTHROBLASTOTIC INFANT

Arrows indicate time of injection of calcium gluconate.

These total 68 mg. as contrasted with 1,020 mg. infused. The infant retained 952 mg. This would indicate a retention of approximately 94% of the citrate injected. Only 71 mg. remained in the blood stream at the end of the procedure when the plasma level was 42.6 mg.%. This is calculated on the assumption of a volume of 275 ml. and a hematocrit of 40%.

Examination of Figures 2-4 indicates that the ability to lower citric acid levels in the plasma is somewhat impaired in the erythroblastotic infants transfused. Cases 4, 5, 7 and 9 show an immediate elevation of citric acid levels after the administration of the first 60 ml. of citrated blood, to a level of more than 30 mg.%. Case 9, who died, showed the highest level at this point (52 mg.%). It is of interest to compare these curves with that of the infant who showed no symptoms of erythroblastosis. Comparison can only be made on the part of the curve obtained before the administration of calcium gluconate, since injection of this material causes changes which will be discussed below.

Each point on the curves represents the addition of 60 ml. of citrated blood. All cases, with the exception of the infant who died (Figure 3) showed spontaneous lowering of citric acid levels in the face of continued administration of citrate. Thus all the cases which survived, with the exception of Case 5, showed lowering of citric acid levels after the initial rise, indicating a more rapid removal at these points than the rate at which the citrate was added. It is of interest to note that Case 5 clinically was the most severely affected of those who survived. Yet it is apparent that this infant's response to the administration of citrate clearly showed a less impaired mechanism than that of the infant who died (Case 9). For example, after 180 ml. of citrated blood had been infused (approximately two-thirds the infant's original blood volume) the citrate level was at 50 mg.%. At this same point in the transfusion Case 9 was at 78 mg.%. Case 9 showed little resistance to the rising citric acid levels. Similar comparison of Case 9 with all the other cases clearly showed the lesser ability of this infant to lower plasma citric acid levels.

The fate of administered citrate is suggested by several experimental studies on animals. Rabbits injected with sodium citrate subcutaneously ex-

hibit an increase in the size of the livers (20). This increase has been demonstrated to be due in part to an increase in liver glycogen following the administration of citric acid (21). It would appear, therefore, that in these cases of exchange transfusion the citric acid may be rapidly converted to glycogen and perhaps lipids.

That the major portion of this conversion takes place in the liver has been shown by the work of Sjöström (22). When livers of rabbits, dogs and cats were perfused with fluids containing sodium citrate in concentrations one hundred times as large as those found in normal sera, after a single passage the perfusate had a citrate concentration near to normal levels for that animal. When rabbit livers were then poisoned by allyl formate, the level of serum citrate rose and the perfused liver showed a markedly diminished ability to metabolize citrate. In confirmation of this, it has been found (23) that the concentration of citrate in the portal vein was regularly higher than that in the arterial blood.

The liver is, however, not the only organ involved in the removal of citrate from the blood stream. The kidney removes and concentrates citric acid. The level of citrate in the urine is approximately 15-50 times that of the serum (11). The concentration of citrate in the renal vein is 20% lower than that in the renal artery (23). Citrate is also metabolized in the musculature. Stoppani (24) has demonstrated rapid metabolism of injected citric acid in eviscerated dogs.

In conjunction with the clinical symptoms and in the light of autopsy findings on children who have died of erythroblastosis fetalis the observations on the lessened tolerance of erythroblastotic infants to administration of citrate may be traced to partial liver damage and perhaps concomitant kidney damage. The liver damage in the infant who died was so extensive, as observed on postmortem examination, that very little resistance could be offered to the rising citric acid values. We postulate, from their ability to remove administered citric acid from the blood stream, that the other infants who showed greater resistance to a rise in citric acid plasma levels, conversely, had lesser liver damage and therefore a greater chance of survival.

At all points where calcium gluconate was injected (Cases 2-9) a rise in citrate level followed.

In this connection it is of interest that injection of calcium salts, or of parathormone to raise the calcium level causes a rise in endogenous citrate levels (25).

That administration of calcium gluconate seems to interfere with the removal of citrate from the blood plasma must not be construed, for obvious reasons, as counterindicating the use of calcium gluconate to prevent tetany during the procedure.

In the case where calcium values were studied during the transfusion (Figure 4) a rise in endogenous calcium was noted before administration of calcium gluconate. This probably comes from the body stores of calcium (skeleton). The response is remarkably rapid. Studies on sheep (26) have shown that injection of citrate causes a rise in serum calcium which drops to normal after the citrate has been removed from the blood stream. Steggerda (27) has shown that oral administration of citric acid will cause a retention of calcium in humans followed later by increase in excretion in the stools. Similarly, it is probably from the bone stores that the phosphorus values are maintained in the face of the continuous administration of citrated blood containing half the inorganic phosphorus found in the infant's serum. The rise of calcium would therefore represent an endogenous mechanism for combatting the lowering of calcium ion concentration when citrate is infused. For the usual exchange transfusion, especially those involving the transfusion of 1,000 ml. of blood this needs to be supplemented by injection of calcium gluconate.

These findings may explain the clinical observations of numerous investigators on the use of citrate as the anticoagulant. Clinical experience with citrate in transfusions seems to indicate that it is a non-toxic anticoagulant (28). Further, large doses of citrate fed to animals over an extended period of time produced no toxic effects (29). The liver, the kidneys, the peripheral musculature and the bone stores all serve to lower citric acid levels or to neutralize their effect on calcium and magnesium ion concentration.

A marked disparity exists between the concentration of various blood constituents in the adult as compared with the newborn. Some of these differences are further enhanced by addition of sodium citrate to adult blood. Other than the change in citrate concentration the addition of 60 ml. of

3% sodium citrate to 500 ml. of blood will raise the total base of the plasma from approximately 150 meq./l to about 175 meq./l (determined as 178 meq./l).⁴ Table I compares the values for phosphorus, protein, total base, calcium and citric acid of the citrated adult blood with the blood plasma of the newborn with no symptoms of erythroblastosis.

Despite the fact that blood with a total base of 178 meq./l was administered rapidly and "flushed through" the circulatory system the total base of the infant's blood remained within the normal range (145-155 meq./l). The protein rise was small and only apparent toward the end of the procedure. One hour after the procedure was ended the protein values were falling, they were below the original fasting level of the newborn 19 hours later. The fall in protein and the appearance of a mild jaundice at the end of 19 hours may indicate some liver damage. Within 48 hours after the procedure the infant showed no untoward effects. Phosphorus levels during and at the end of the transfusion remained close to that of the infant's pre-transfusion blood rather than assuming the phosphorus level of the donor's blood.

From the observations above it is apparent that citrate as an anticoagulant has advantages. When infused, as in an exchange transfusion, into the newborn it is readily metabolized and removed from the blood stream restoring the natural clotting capacity of the blood within one hour after the transfusion is complete. However, a reasonable amount of liver and kidney function must be present to make possible the removal of citrate, the readjustment of total base, protein and phosphorus levels to their natural level for the newborn.

Using the icterus index and low protein level as criteria, observed in the control 19 hours after the transfusion, it must be said that some temporary

⁴ 500 ml. of adult blood would contain 300 ml. of plasma assuming a hematocrit of 40%. With a total base of 150 meq./l, 300 ml. of plasma would contain 45 meq. The molecular weight of the dihydrate of sodium citrate is 295. For our purposes it may be assumed to be 300 so that a 3% solution would contain 100 millimoles/l or 300 meq./l. Sixty ml. of this solution would contain 18 meq. The total plasma volume of the 500 ml. of citrated blood would then be $300 \div 60 = 360$ ml. In this volume would be contained $45 \div 18 = 63$ meq. Expressed in meq./l the citrated plasma would contain 175 meq./l.

liver damage is produced in this process. However, in the infant with no symptoms of erythroblastosis recovery was observed 48 hours after the transfusion with return to normal icterus and protein level.

SUMMARY

1. Exchange transfusions were carried out on one mongoloid newborn with no symptoms of liver damage or erythroblastosis and on eight newborns suffering from erythroblastosis fetalis.

2. Serial studies done on the blood removed from the normal infant showed an effective homeostatic mechanism to be operative in the case of citrate, total base, phosphorus and total protein.

3. Administration of calcium gluconate interferes with the rate of citrate removal from the blood stream.

4. The liver, kidneys, musculature and bone stores appear to remove or neutralize the effect of high citrate levels in the blood stream.

5. The erythroblastotic infants showed impaired ability to remove citrate but showed themselves still capable of removing massive quantities of citrate from the blood stream.

6. With the exception of one case all infants seemed to metabolize citric acid more rapidly or at least as rapidly as it was infused in the early stages of the transfusion. In this case where the disease process was most severe citric acid levels rose steadily throughout the transfusion. The infant died within 24 hours.

The authors would like to express their appreciation to Dr. A. S. Wiener who kindly permitted us to use his cases for this study.

ELECTROLYTE CHANGES IN HUMAN STRIATED MUSCLE IN ACIDOSIS AND ALKALOSIS

By GILBERT H. MUDGE¹ AND KATHERINE VISLOCKY

(From the Department of Medicine, College of Physicians and Surgeons, Columbia University,
and The Presbyterian Hospital in the City of New York)

(Received for publication October 14, 1948)

INTRODUCTION

In recent years many studies have been reported on the monovalent cation composition of the intracellular space during experimentally produced potassium depletion. The most consistent changes have been found in striated muscle and, in general, have shown that decreased concentrations of intracellular potassium are associated with an increase in intracellular sodium. Such changes have been reported in the rat (1), the cat (2), and the dog (2) following low potassium diets. The administration of desoxycorticosterone acetate in large doses has produced similar changes in the same animals (2-4). Recently Darrow has reported comparable findings in association with alkalosis, as determined by muscle analyses in rats (5) and indirectly by balance studies in man (6).

Inasmuch as direct studies of human tissues during states of potassium depletion have not been reported, the present studies were undertaken in an attempt to define the composition of the intracellular electrolytes of striated muscle obtained by biopsy from patients with metabolic alkalosis and acidosis.

METHODS

Biopsies. Muscle biopsies were taken from the hamstring or gastrocnemius muscles, the average weight of fresh tissue being 2.4 gms. Anesthesia was obtained by infiltration of the skin and subcutaneous tissues with 2 per cent procaine in saline. Careful precautions were taken to avoid infiltration of the muscle tissue with the anesthetic agent and it is believed that there was no contamination of the specimens with the possible exception of two cases (Table I, patients G. and To.). In these patients inadequate anesthesia necessitated infiltration of the muscle approximately 10 cm. proximal to the site from which the actual biopsy was taken. A careful analysis of the results obtained from these two specimens reveals no abnormality specifically attributable to the possible inclusion of the anesthetic solution in the specimen, and it is

therefore believed that no contamination occurred. Excess blood was removed by blotting the specimen with dry gauze. The tissue was immediately placed in an airtight glass container and analytical procedures were begun within one hour. Venous blood specimens without stasis were taken under oil at the time of biopsy.

"Normal" control muscle specimens and accompanying blood samples were obtained from patients undergoing operations under general anesthesia (Table I), the biopsies being taken from the rectus abdominalis at the start of the operation. The patients had been on a normal diet, had not received previous parenteral alimentation, and were considered to be in a normal state of fluid and electrolyte balance. The alleged normalcy of the control muscles may be subject to question because of possible changes resulting from the anesthetic agents or the underlying disease process. Minor changes may also have resulted from sustaining infusions of glucose and saline started at the time of operation. However, the "normal" values obtained are in essential agreement with previously reported analyses of human skeletal muscle (7), and because of the marked differences between the "normal" and abnormal groups, it is felt that these tissues represent an adequate control for the present study.

Analytical Methods. Determinations were made of the concentration of water, fat, chloride, sodium, potassium, and nitrogen in the tissues. All analyses were done in duplicate. The analytical procedure was that of Lowry and Hastings (8) as modified by Hull (9), with additional modifications for determination of sodium and potassium by an internal standard flame photometer (10). The fresh tissue was freed of all visible fat and connective tissue and then finely minced with scissors and placed in a 10 cc. volumetric tube. The water content was measured by drying in an electric oven at 105-110° C. to constant weight. Neutral fat was determined by the extraction with ethyl ether of the residue remaining after the evaporation of water, according to the procedure of Hastings and Eichelberger (11). The extracted fat and solvents were returned to the tube and the solvents evaporated. The tissue was digested in a bath of boiling water with 3 ml. concentrated nitric acid in the presence of silver nitrate 50 per cent in excess of anticipated chloride. Chloride content was determined by Volhard titration of an aliquot of the digest made up to volume with water. Sodium and potassium were determined on 1 or 2 cc. aliquots diluted to the proper volume with the addition of lithium sulfate as an internal standard. Flame photometry yielded an accuracy of 1 per cent, and large

¹ National Research Council Fellow.

excesses of nitric acid and inorganic phosphate added to standard solutions introduced no measurable error. Nitrogen estimations were done on samples of tissue separate from those taken for electrolyte analysis, and nitrogen was determined by micro-Kjeldahl technique. All analyses were corrected for fat-free weight, including nitrogen estimations for which it was assumed that the fat content was the same as in the aliquot used for electrolyte determinations. Duplicate analyses of separate aliquots of minced muscle from 42 specimens analyzed by this method have shown the following average percentile deviation from the mean values: water $\pm 0.2\%$; chloride $\pm 1.9\%$; sodium $\pm 1.5\%$; potassium $\pm 1.2\%$; and nitrogen $\pm 0.9\%$.

Serum electrolytes were determined by methods previously reported (3), except that sodium and potassium were determined by flame photometry. Serum pH was determined by glass electrode.

Calculations. Serum concentrations were corrected for serum water which was either determined directly by drying to constant weight at 110°C , or estimated from serum protein concentration (8). Extracellular concentrations of sodium, potassium and chloride were calculated using an average Donnan factor of 0.95. Extracellular water (ECW) was calculated as the "chloride space." Intracellular electrolytes were obtained as the difference between tissue and extracellular values and have been expressed in concentrations per liter of intracellular water (ICW). Because tissue hemoglobin, collagen and elastin were not measured, all tissue nitrogen was considered as intracellular, thus introducing a small systematic error of less than 1 per cent (8). For comparative purposes nitrogen has been expressed as grams per liter ICW.

RESULTS

Nine patients were studied—three controls, three with gastric alkalosis, and three with chronic renal acidosis without glomerular insufficiency (12). The results are given in Table I. The last two analyses of patient R. have been excluded from the present discussion because blood specimens were not taken simultaneously with the muscle. Calculated intracellular sodium averaged 8 mEq/L ICW in the control group. There is no apparent explanation for the variation of the values within the control group. Both the patients with acidosis and alkalosis showed an increase of intracellular sodium, average values being 32 mEq/L ICW for the acidosis group and 20 mEq/L ICW in alkalosis. Serum potassium varied from 3.9 to 4.8 mEq/L for the controls, from 2.5 to 3.7 mEq/L for the acidotic group, and from 1.8 to 2.7 mEq/L for the alkalotic group. The increase in intracellular sodium was proportional to the decrease

FIG. 1. CLINICAL COURSE, SERUM ELECTROLYTES, AND INTRACELLULAR ELECTROLYTES IN PATIENT R. SHOWING DEVELOPMENT OF INTRACELLULAR POTASSIUM DEPLETION WITH SODIUM REPLACEMENT AS PROLONGED ALKALOSIS WAS TREATED WITH PARENTERAL SODIUM CHLORIDE SOLUTIONS

in intracellular potassium as is indicated by the constancy of the sum of the concentrations of these two cations, average values being 165 mEq/L ICW for the controls, 163 mEq/L ICW for the acidotic subjects and 163 mEq/L ICW for the patients with alkalosis. The widest variations of these values was found in the group with alkalosis. The ratio of nitrogen to cell water indicates a relative cellular dehydration in acidosis with a slight increase in hydration in alkalosis. However, the changes in cellular hydration are small and are not definitely conclusive.

The most striking abnormalities were found in the serial analyses of patient R. (Table I and Figure 1) who had persistent vomiting due to a carcinoma of the duodenum. During 63 days he received 239 L of parenteral fluids, therapy being primarily directed towards the maintenance of a normal hematocrit and normal concentrations of serum sodium, chloride and protein. Random analyses revealed a continuous loss of potassium in vomitus and urine. No parenteral potassium was administered. Although the calculation of the intracellular space in the last two muscle analyses can only be accepted as an approximation because

the blood and muscle specimens were not simultaneous, the muscle specimens obtained at operation and autopsy showed, respectively, that 40 per cent and 31 per cent of the intracellular cation was sodium. The serum values for the autopsy

specimen were obtained six hours before death, the autopsy being performed 11 hours post mortem. The extent to which post mortem changes may have modified the calculated intracellular values cannot be accurately evaluated at present.

DISCUSSION

The calculation of the extracellular and intracellular spaces and the electrolytes contained herein has been based on the concept either that all chloride is extracellular (11, 13, 14), or that a small but invariable amount of chloride is intracellular (15). Because of inadequate data on human muscle, the possibility of a small constant quantity of chloride within cells has been neglected. However, the obligatory extracellular position of chloride has been challenged by recent experiments in which large doses of potassium chloride were administered (16, 17). An analysis of the results reported here indicates that the chloride content of whole muscle varies directly with the serum chloride concentration. Small deviations from an exactly linear relationship may so easily be explained by slight variations in the extracellular fluid volume that we are led to believe that there is no significant alteration in muscle cell permeability to the chloride ion during disturbances of the type reported here. We therefore feel that the use of the chloride space as a measure of the extracellular space is valid for these studies.

Although the number of specimens is too small to warrant definitive statistical analysis, it is apparent in the conditions studied that there has been a loss of intracellular potassium from striated muscle with an increase in intracellular sodium. The human, therefore, responds in a manner qualitatively similar to other species studied.

In recent studies Darrow *et al.* (18) have demonstrated a correlation between alkalosis and a rise in intracellular sodium in the presence of normal renal function. In acidosis produced by the administration of ammonium chloride to rats, they found a decrease in the amount of sodium within striated muscle cells. Although our studies of acidosis have been limited to a single disease, namely, chronic renal acidosis without apparent glomerular insufficiency, the fact that these patients demonstrate a significant depletion of intracellular potassium and a rise in intracellular sodium in the presence of systemic acidosis indicates that these changes are not necessarily associated with alkalosis of the body fluids. Albright *et al.* (12) showed that this type of renal abnormality was associated with a negative potassium balance, which has been confirmed by

unreported balance studies of two of our patients. These findings, therefore, suggest that the described abnormalities in the intracellular electrolyte pattern may not be specifically related to changes in acid-base equilibria, but rather are a reflection of an overall negative potassium balance, regardless of the immediate cause.

The relationship of disturbances in potassium metabolism to paralysis has been recently reviewed (19). Of our six cases with documented potassium depletion, only one patient developed paralysis (subject G., Table I). On the day of biopsy the patient was unable to walk, feed herself, or turn over in bed. The paralysis had developed gradually during the preceding days and had not been precipitated by a large carbohydrate intake. Serum potassium was 2.5 mEq/L, a value of 2.6 having been obtained on the second and sixth day before the episode of paralysis. Following the administration of parenteral and oral potassium chloride the patient rapidly improved with disappearance of all symptoms of paralysis. During the following two weeks of observation, the serum potassium ranged from 2.8 to 3.2 mEq/L. Although a spontaneous remission cannot be absolutely ruled out, the fact that the paralysis disappeared following the administration of potassium chloride is evidence that the disturbed neuromuscular function was actually caused by a potassium deficit. It is of particular interest, therefore, that the concentrations of potassium in the serum and muscle of this patient were not significantly different from those of the others studied. The findings in patient P. (Table I) were almost identical, yet she had no paralysis. On the other hand, patient R. (Table I) showed the greatest potassium depletion, but throughout his hospital course had no manifest disturbances of neuromuscular function. Our limited observations thus fail to reveal any correlation between potassium concentration within skeletal muscle and the appearance of paralysis.

CONCLUSIONS

1. The association of alkalosis with decreased concentrations of intracellular potassium and increased concentrations of intracellular sodium has been confirmed by analysis of biopsies of human striated muscle.

2. Similar changes have been observed in patients with systemic acidosis due to chronic renal disease.

3. One patient with severe paralysis attributed to potassium deficit showed intracellular changes which were quantitatively not different from the non-paralyzed patients.

STUDIES ON FREE ERYTHROCYTE PROTOPORPHYRIN, SERUM IRON, SERUM IRON-BINDING CAPACITY AND PLASMA COPPER DURING NORMAL PREGNANCY¹

By JANE FAY, G. E. CARTWRIGHT, AND M. M. WINTROBE

(From the Department of Medicine, College of Medicine, University of Utah, Salt Lake City)

(Received for publication November 2, 1948)

Changes in the free erythrocyte protoporphyrin, plasma iron, serum iron-binding capacity and plasma copper in normal individuals and in various diseases associated with anemia have been investigated previously in this laboratory (1). The present observations were carried out to determine the "chemical pattern" of the blood in the pregnant state.

METHODS

The hematological methods used have been described previously (2). Free erythrocyte protoporphyrin was measured according to the method of Grinstein and Watson (3). The method of Barkan and Walker (4) was used for the measurement of serum iron. The iron-binding capacity of the serum was determined by a modification (5) of the method of Schade and Caroline (6). Plasma copper was determined according to the procedure of Cartwright, Jones and Wintrobe (7).

Eighty-six pregnant women were studied. The determinations were made at monthly intervals during pregnancy and the postpartum period. Thirty-one women were studied only once, 32 were followed for two months, 15 for three months, five for four months, and three for five months. In the entire study 139 determinations of packed red cells were made, 89 erythrocyte protoporphyrin determinations, 137 serum iron determinations, 129 plasma copper determinations, and 74 determinations of the serum iron-binding capacity. Sixteen women received ferrous sulfate by mouth during a part of the study. The values in this group showed no significant deviation from those in patients not receiving specific therapy. Nevertheless, the values obtained during the period of iron administration have not been included in the data presented in the figures. Placental blood was collected from the umbilical vein immediately after delivery of the placenta.

In this laboratory, the following are the values found in normal females: serum iron $104.3 \pm 36.4 \mu\text{g}$ per cent, iron-binding capacity of the serum $371 \pm 35.9 \mu\text{g}$ per cent, plasma copper $122.7 \pm 10.6 \mu\text{g}$ per cent (1). Observed values for free erythrocyte protoporphyrin have shown a skew distribution and the geometric mean \pm two standard deviations has been found to be 34 (14 to 83)

$\mu\text{g}/100 \text{ ml.}$ of red blood cells. The normal subjects were not usually examined completely but they were apparently healthy and the hematologic determinations including the red cell indices were within normal limits in all instances.

RESULTS

Volume of packed red cells. The changes in the volume of packed red cells during pregnancy can be seen in Figure 1. During the first trimester, there was little deviation from the normal mean.

FIG. 1. VOLUME OF PACKED RED CELLS (VPRC) DURING PREGNANCY AND THE POSTPARTUM PERIOD

This was followed by a gradual decrease in the percentage of packed red cells. The lowest values were obtained in the last trimester, during the latter half of which the mean was found to be 37.9 ml./100 ml. as compared with 42.5 during the first trimester. During the postpartum period a return to values found in non-pregnant women took place within the first two months.

Erythrocyte protoporphyrin. The trend of the free erythrocyte protoporphyrin during pregnancy can be seen in Figure 2. There appeared to be a slight increase in the mean value during each successive month but only five determinations were above, and only slightly above, the upper limit of normal.

Analysis of the relationship of the free erythrocyte protoporphyrin and the mean corpuscular

¹ Aided by grants from the United States Public Health Service and the Upjohn Company, Kalamazoo, Michigan.

FIG. 2. FREE ERYTHROCYTE PROTOPORPHYRIN (EP) DURING PREGNANCY AND THE POSTPARTUM PERIOD

hemoglobin concentration during the last trimester of pregnancy, reveals a correlation coefficient of -0.54 . However, since the mean corpuscular hemoglobin concentration ranged only from 31 to 37 per cent with two-thirds of the values 33 or 34 per cent, this correlation cannot be regarded as significant.

Serum iron. In Figure 3, the values for serum iron are presented. In the first trimester, no change was observed. After this, there was a gradual decrease in the mean, reaching the lowest value in late pregnancy. Within the first three months of the postpartum period a return to normal occurred. There were wide individual variations at all stages.

Iron-binding capacity. The changes in the total iron-binding capacity of the serum are presented in Figure 4. The values during the first 20 weeks were found to be within normal limits. During the second half of pregnancy the iron-binding ca-

FIG. 3. SERUM IRON (SI) DURING PREGNANCY AND THE POSTPARTUM PERIOD

capacity increased; the highest values were found in the last trimester. Within eight weeks after delivery, normal values were again attained. It should be noted that the iron-binding capacity increased at the time the serum iron diminished and the iron-binding capacity curve is the reciprocal of the serum iron curve.

Plasma copper. The results of the determinations of plasma copper are shown in Figure 5. Of the chemical constituents studied this was the first to change during pregnancy. The copper content of the plasma became elevated early in pregnancy and increased steadily until the third trimester, during which period it remained at a maximum until delivery. During the first two months of the postpartum period the values returned to the normal level.

FIG. 4. TOTAL IRON-BINDING CAPACITY OF THE SERUM (TIBC) DURING PREGNANCY AND THE POSTPARTUM PERIOD

Placental blood. The placental and maternal serum iron and plasma copper are compared in Table I. The specimens were taken from the mothers at the time of delivery. As can be seen, the values for copper were considerably higher in the maternal blood than in the placental blood

TABLE I

whereas the converse was true in regard to serum iron.

DISCUSSION

Certain alterations from the normal in copper, iron and iron-binding capacity of the serum have been observed during pregnancy, while no significant change has been found in free erythrocyte protoporphyrin. The results are summarized in Table II. The earliest change noted was an elevation in the plasma copper. This was followed in the middle of the second trimester by a decrease in the

serum iron and a corresponding increase in the serum iron-binding capacity. The greatest changes in all three of these values were observed in the last trimester. In Table III morphologic and chemical studies on 22 women during the last trimester of pregnancy are given in detail. These findings are in accord with those of others (8-13).

The changes noted during pregnancy differ in certain respects from those observed in various types of anemia (1). Thus, although as in the anemia associated with iron deficiency there was an increase in plasma copper, a decrease in serum iron and an increase in the iron-binding capacity of the serum, the serum iron values in pregnancy did not reach the extremely low levels seen in iron deficiency nor was there the marked increase in the free erythrocyte protoporphyrin seen in iron deficiency anemia. The chemical pattern does not correspond to that observed in the anemia of infection, where an increase in erythrocyte protoporphyrin and a decrease in iron-binding capacity of the serum occurs. Even in the presence of infection, the iron-binding capacity during pregnancy was found to remain elevated.

The increase in iron-binding capacity during the latter half of pregnancy occurs at a time when the demand for iron on the part of the fetus is greatest. The present observations reveal a close time correlation between the decrease in serum iron and the increase in iron-binding capacity. If the changes in these values were a function of variations in plasma volume, the deviations would of course be in the same direction. It may be that the elevation in the iron-binding capacity is part of the mechanism for increased iron absorption, mobilization and placental transfer and is analogous to the increase in iron-binding capacity of serum in iron-deficient states.

The elevation in plasma copper would seem to be independent of the changes in iron since there is no correlation in time or degree between these two values. One explanation that has been offered for the high values in the maternal blood is that the elevation of copper is related to the mechanism for mobilization of the element for placental transfer. This theory is based on the fact that copper storage in the tissues of the fetus, especially in the liver, is much greater than in the adult (14-16). It has been observed also that the copper content of placental arterial blood is greater than that of placental venous blood by 30 per cent (17). This suggests that there is a constant withdrawal of copper from the maternal blood via the placenta and storage in the fetus. It seems strange, however, that the high copper content of the fetal tissues should be associated with a low fetal plasma copper, while the high iron content of the fetal

tissues is accompanied by a high serum iron in the fetus and a low serum iron in the mother.

A relationship between the elevated basal metabolic rate in pregnancy and the increased plasma copper has been suggested (13). Hypercupremia has been noted in non-pregnant patients with increased metabolism (9, 18). An elevation in serum precipitable iodine has been observed during pregnancy (19) over the same period of time in which an elevation of plasma copper was found in this study. Both of these changes are evident before there is a change in the basal metabolic rate. It is possible that the elevation in plasma copper is related to changes in endocrine equilibrium during pregnancy. It is clear that additional knowledge concerning the metabolism and functions of copper is needed before conclusions can be drawn concerning its significance in various clinical conditions.

SUMMARY

The free erythrocyte protoporphyrin, serum iron, serum iron-binding capacity, and plasma copper have been measured in 86 normal pregnant women. A decrease in the volume of packed red cells was noted in the latter part of pregnancy. There was no significant change in the free erythrocyte protoporphyrin, although a slight elevation of the mean was found during the later phase of pregnancy. A diminution in serum iron was evident during the latter part of pregnancy and at the same time the iron-binding capacity of the serum increased. Plasma copper values increased during the first trimester and remained elevated during the course of pregnancy. Normal values were regained during the first two months postpartum. Study of placental blood revealed low values for plasma copper while the serum iron level was higher than the corresponding values in the maternal blood.

ACKNOWLEDGMENTS

We are indebted to Miss Betty Tatting, Mrs. Darlene Kehl, Miss Mary Iles and Miss Pauline Black for technical assistance.

We wish to express our appreciation to Dr. Emil G. Holmstrom, Professor of Gynecology and Obstetrics, for his enthusiastic cooperation in this study.

STUDIES ON THE ACTIVATION OF A SERUM "PROTHROMBIN-CONVERTING FACTOR"

By RALPH F. JACOX¹

(From the Department of Medicine of the University of Rochester School of Medicine and Dentistry, Rochester, New York, and the Medical Clinic of the Strong Memorial and Rochester Municipal Hospitals)

(Received for publication November 2, 1948)

Recent reports of additional factors operating at the first stage of blood coagulation have stimulated investigators to explore in greater detail the mechanism by which prothrombin is converted to thrombin.

This report describes a new experimental approach to the problem of prothrombin conversion which, it is felt, may help to clear up some of the complexities of this reaction. In the present study, it will be shown that thromboplastin added to human serum is able to activate a substance which will be called a "prothrombin-converting factor." When thromboplastin is added to serum, the activated factor added to plasma then converts prothrombin to thrombin in the absence of ionized calcium. After initial activation of serum by thromboplastin, the "prothrombin-converting factor" undergoes gradual decay until the serum-thromboplastin mixture is no longer reactive. "Prothrombin-converting factor" can then be repeatedly reactivated from the same serum-thromboplastin mixture by addition of more thromboplastin. When serum obtained from patients treated with dicumarol is activated by thromboplastin, a more prolonged action of the released "prothrombin-converting factor" results.

The mechanism by which these observed reactions are brought about is discussed and a modification of current concepts relating to prothrombin conversion is proposed.

Investigators from different laboratories have utilized diverse methods to arrive at the conclusion that there exist in plasma previously unrecognized factors which initiate the conversion of prothrombin to thrombin. When Seegers *et al.* (1) studied purified prothrombin, they observed that a slowed rate of prothrombin conversion occurred after the reaction was initiated by adding thromboplastin and calcium. At first this retarded

conversion was thought to be related to denaturation of prothrombin attendant upon chemical procedures necessary for fractionation and purification. Later Ware *et al.* (2, 3) and Fantl and Nance (4) were able to produce acceleration of thrombin formation from this purified prothrombin fraction, when serum was added to the prothrombin, thromboplastin and calcium reaction mixture. The protein fraction responsible for accelerating prothrombin conversion was called accelerator globulin (ac-globulin). Ware *et al.* (3) believed that ac-globulin produced a reaction of co-autocatalysis, wherein thrombin accelerates its own formation through an intermediate action of ac-globulin. A minute amount of thrombin produced early in coagulation of blood, liberates accelerator globulin which then intensifies the rate of thrombin formation from prothrombin.

Milstone (5, 6) reported another plasma globulin fraction, prothrombokinase, which is capable of forming thrombin from prothrombin. Prothrombokinase is activated by calcium to form an active thrombokinase which then converts prothrombin to thrombin. Activation of the thrombokinase follows an autocatalytic reaction, requiring considerable time before maximum thrombokinase activity is reached.

Quick (7, 8) postulated the existence of prothrombin A and a labile factor to explain certain discrepancies occurring in prothrombin determinations made by his method. He found that certain plasmas with a low concentration of prothrombin could be restored to a higher concentration following the addition of de-prothrombinated plasma from a normal individual. These observations suggested that some plasmas might be deficient in prothrombin A or a labile factor.

On the basis of studies made on a patient with an unusual type of prothrombin deficiency that could likewise be restored by addition of de-pro-

¹ Henry C. Buswell Research Fellow.

thrombinated plasma from a normal individual, Owren (9) postulated a different interpretation of results. He assumed that normal blood plasma contains an activator substance for prothrombin which he calls Factor VI. Factor VI exists as an inactive pro-enzyme Factor V which can be activated by thromboplastin and calcium in the presence of prothrombin to form Factor VI. Factor VI thereupon causes an enzymatic conversion of prothrombin to thrombin.

With these divergent interpretations and definitions in mind, it has seemed logical in the experiments to be reported, to speak of the factor in serum, which is activated following the addition of thromboplastin, as "prothrombin-converting factor." It may be that the "prothrombin-converting factor" is synonymous with Factor VI of Owren (9), thrombokinase of Milstone (6), prothrombin A and labile factor of Quick (7, 8) and accelerator globulin of Ware *et al.* (3).

EXPERIMENTAL METHODS

Collection of serum: Blood samples were collected from normal individuals and patients hospitalized for miscellaneous diseases. Dry syringes were used to obtain the blood and all collections were made as quickly as possible to avoid incipient coagulation. The plasma was prepared by adding 9.0 cc. of whole blood to 1.0 cc. of 0.1 M sodium oxalate solution. Serum was prepared by allowing whole blood to coagulate in glass tubes with internal dimensions of $\frac{5}{8} \times 6$ inches. Approximately 45 minutes later, the clot was rimmed with a wooden applicator and the serum, after centrifugation, was separated from the clot.

Preparation of thromboplastin: Dried thromboplastin was prepared according to Quick's method (10). Both human and rabbit brain preparations were utilized without any apparent difference in the results. Fresh thromboplastin suspension was made each day by mixing 0.3 gm. of dried brain powder with 5.0 cc. of 0.85 per cent sodium chloride solution. The thromboplastin suspension thus prepared was shaken periodically for 20 minutes at 50° C. after which, gross particles of brain were removed by centrifugation for three minutes at 1,000 R.P.M. Thromboplastin suspension prepared in this manner produced coagulation of recalcified, fresh, oxalated human plasma in 17–20 seconds at room temperature (22° C.).

Method of activating the serum "prothrombin-converting factor": Serum to be tested was allowed to remain at room temperature for two to three hours to allow destruction of thrombin activity to take place. Thrombin activity of serum was measured by adding 0.2 cc. of serum to 0.2 cc. of fresh plasma. Coagulation of the plasma usually did not occur until four or five minutes had elapsed. Serum capable of coagulating plasma in less

than four minutes was not used in the tests reported. Many of the sera were also tested for prothrombin activity by adding 0.1 cc. of serum to 0.1 cc. of fibrinogen and 0.1 cc. of thromboplastin suspension. The coagulation time of this mixture was usually greater than 180 seconds indicating that an insignificant amount of prothrombin remained.

Following these preliminary experiments to insure that the serum did not contain substances interfering with the test, activation of the "prothrombin-converting factor" was accomplished in the following manner:

Five-tenths cc. portions of serum were added to 0.1 cc. portions of thromboplastin suspension and thoroughly mixed. Simultaneously a stop-watch was started and at exactly one, three, seven, and 15 minute intervals, 0.1 cc. of the serum-thromboplastin (serum-TP) mixture was withdrawn into a 1.0 cc. pipette, calibrated to the tip, and blown into 0.1 cc. of plasma. The coagulation time of the serum-thromboplastin-plasma mixture was then determined to the nearest second. All of these operations were carried out at room temperature (22° C.). All coagulation tests were made in glass tubes with internal dimensions 12 × 25 mm. The coagulation time was determined as the point at which the plasma-serum-thromboplastin mixture first showed visible fibrin formation as the glass tube was tilted gently up and down from a diagonal position. A similar dilution of thromboplastin was made in 0.85 per cent sodium chloride solution to which sufficient calcium chloride had been added to produce a molarity of calcium ion corresponding to the ionized calcium of serum (0.0012 M). When this suspension was added to the plasma containing 0.01 M sodium oxalate, no coagulation occurred.

Since no calcium had been added to serum prior to the addition of thromboplastin, it is evident that the coagulating action of the serum-TP mixture could not be related to a direct effect of thromboplastin on the prothrombin of the plasma.

Effect of addition of thromboplastin to serum: The kinetics of the reaction taking place after addition of thromboplastin to serum are presented in Figure 1, which shows the results obtained from activation of sera from three normal individuals on three successive days. One minute after the introduction of 0.1 cc. of thromboplastin suspension to 0.5 cc. of serum, 0.1 cc. of the mixture added to 0.1 cc. of plasma produced coagulation in eight to 13 seconds. After three minutes incubation of the serum-TP mixture, plasma was coagulated in 12–19 seconds. Seven minutes' incubation of the serum resulted in plasma coagulation in 27–41 seconds following the addition of 0.1 cc. of this mixture to 0.1 cc. of plasma; while incubation for 15 minutes resulted in a plasma coagulation time of 50–80 seconds. If the serum-TP mixture was allowed to react several hours, no coagula-

COMPILATION OF RESULTS OF SERUM REACTION CURVES FROM THREE
NORMAL INDIVIDUALS ON THREE SUCCESSIVE DAYS

Fig. 1

The coagulation time of oxalated plasma, following the addition of serum-thromboplastin mixture, is indicated on the ordinate. The incubation time of the serum-thromboplastin mixture before it is added to oxalated plasma is indicated on the abscissa. Observe that maximum activation of serum occurs within one minute of the time of adding thromboplastin, following which, there is a slow decay of coagulating power of the serum-thromboplastin mixture.

tion of the plasma occurred when the serum-TP mixture was added to plasma. However, if 0.1 cc. of inactive serum-TP mixture was mixed with 0.1 cc. of plasma and 0.1 cc. of 0.02 M CaCl_2 then added, coagulation occurred as rapidly as when an identical amount of thromboplastin alone was added to plasma along with 0.02 M CaCl_2 . Furthermore, addition of the inactive serum-TP mixture to fresh serum caused activation of a "prothrombin-converting factor" to the same degree as thromboplastin correspondingly diluted in saline and mixed with serum. These experiments indicate that the thromboplastin is still active in the serum-TP mixture, but has apparently been altered in some manner so that activation of the "prothrombin-converting factor" no longer takes place.

If serum is activated by thromboplastin and then the mixture is added to either de-prothrombated plasma or fibrinogen (Figures 2 and 3), little or no coagulation is produced, indicating that the mechanism of coagulation of the normal plasma cannot be related to a thrombin effect. A mixture of thromboplastin in 0.0012 M CaCl_2 in physiological saline which reproduces the molarity of ionized calcium in the serum, does not produce coagulation of plasma containing 0.01 M oxalate, so that one cannot relate the coagulating action of the serum-TP mixture to the thromboplastin and calcium content of the mixture.

EFFECT OF ADDING SERUM-THROMBOPLASTIN TO
FIBRINOGEN AND PROTHROMBIN

FIG. 2. EFFECT OF ADDING A SERUM-THROMBOPLASTIN MIXTURE TO FIBRINOGEN AND FIBRINOGEN-PURIFIED PROTHROMBIN SOLUTIONS

The ordinate indicates the coagulation time of the various fibrinogen preparations, following addition of serum-thromboplastin. The abscissa indicates the incubation time of the serum-thromboplastin mixture before it is added to the fibrinogen solutions. The uppermost broken line represents the results obtained when fibrinogen alone was used; while the solid lines show the results obtained when varying amounts of prothrombin were added to fibrinogen. The bottom broken line shows the effect of adding the same serum-thromboplastin mixture to fresh oxalated plasma containing a prothrombin concentration 100 per cent of normal.

The maximal coagulating action of the activated serum appears one minute after addition of thromboplastin. At this point plasma is coagulated much more rapidly than one would expect if one added only thromboplastin and calcium to plasma to determine the prothrombin time. From this evidence it can be assumed that addition of thromboplastin to serum initiates a reaction which causes liberation of a substance which in turn is capable of converting prothrombin to thrombin.

EFFECT OF VARYING CONCENTRATIONS OF PROTHROMBIN IN PLASMA

FIG. 3

Prothrombin was adsorbed from plasma with BaCO_3 . Aliquots of fresh plasma were then added to the BaCO_3 -treated plasma to produce the desired concentration of prothrombin. The coagulation time of plasma after addition of the serum-thromboplastin mixture (ordinate) was then plotted against the incubation time of the serum-thromboplastin mixture (abscissa). A decreasing concentration of prothrombin in the plasma is associated with a more abrupt decay of the activated serum's power to coagulate plasma. The broken-line curve was obtained by activating serum from a patient treated with dicumarol whose plasma prothrombin concentration was 20 per cent of normal. This serum, activated by thromboplastin, was then added to a BaCO_3 -treated plasma containing 10 per cent prothrombin. A striking difference in the activation curve is apparent.

REACTIVATION OF THE SERUM-THROMBOPLASTIN MIXTURE

FIG. 4. REACTIVATION OF A SERUM-THROMBOPLASTIN MIXTURE BY INCREMENTS OF THROMBOPLASTIN

One cc. of serum was added to 0.2 cc. of thromboplastin. Thirty minutes later, 0.1 cc. of this mixture was added to 0.1 cc. of oxalated plasma and the coagulation time recorded. An additional 0.1 cc. of thromboplastin was then added to the initial serum-thromboplastin mixture and one minute later, 0.1 cc. of this was withdrawn and added to oxalated plasma. The curve of decay of the serum-thromboplastin coagulating substance is interrupted by addition of fresh thromboplastin. The serum-thromboplastin mixture can be repeatedly reactivated as shown in this graph.

The serum-thromboplastin mixture produces no coagulation of plasma, after a sufficient period of incubation of the serum and thromboplastin has taken place. Reactivation of the serum component can be produced, however, when fresh thromboplastin is added to the inactive serum-TP mixture. After serum and thromboplastin were allowed to react for 30 minutes, it was found that 0.1 cc. of this mixture produced coagulation of 0.1 cc. of plasma in 120 seconds. An additional 0.1 cc. of thromboplastin was then added to the above serum-TP mixture. One minute later 0.1 cc. of the new serum-TP mixture coagulated 0.1 cc. of plasma in 20 seconds, demonstrating that the clotting activity of the serum-TP mixture had been almost completely restored. As shown in Figure 4, alternating decay and reactivation were ob-

served many times. It appears that the activated serum factor capable of producing plasma coagulation is not destroyed but only reversibly inactivated. It can be reactivated repeatedly, merely by adding more thromboplastin to the serum.

Effect of adding activated serum to "artificial plasmas": The clotting activity of a "prothrombin-converting factor" of serum, activated by thromboplastin, was further studied by observing the effect of adding activated serum to fibrinogen solutions.

Human fibrinogen² was dissolved in 0.85 per cent sodium chloride solution (pH 7.5) to make a concentration of fibrinogen of 200–300 mg. per cent. It will be observed in Figure 2, that serum-TP mixture coagulated fibrinogen in 110 seconds in contrast to a coagulation time of 10 seconds for plasma (bottom broken line). After incubation for three minutes, the serum-TP mixture produced no coagulation of fibrinogen as compared to a coagulation time of 28 seconds for the plasma.

A preparation of purified prothrombin² was then added to the fibrinogen solution as follows: Prothrombin was dissolved in 0.85 per cent sodium chloride solution, adjusted to pH 7.5. Aliquots of this solution, representing a known amount of prothrombin, were then added to the fibrinogen solution. Serum activated by thromboplastin was then added to the different solutions of fibrinogen and prothrombin and the coagulation times were recorded. It will be observed from Figure 2 that the reaction curves produced by adding prothrombin to fibrinogen approximate the same type of curve that is obtained when normal plasma is used.

Plasma was prepared to contain varying amounts of prothrombin by the following method: Fresh plasma was freed of prothrombin by adding it to powdered BaCO₃ (method of Fantl and Nance [4]). The plasma and BaCO₃ were shaken vigorously and allowed to react for 20 minutes. The plasma was then freed of BaCO₃ by rapid centrifugation. The supernatant, clear plasma was removed and tested for prothrombin activity by adding thromboplastin and 0.02 M CaCl₂. Complete removal of prothrombin was evident since the adsorbed plasma failed to coagulate. Sufficient

fresh plasma was then added to aliquots of the BaCO₃-treated plasma to produce a 10 per cent, 20 per cent, 30 per cent, and 50 per cent prothrombin concentration in the plasma utilized in experiments presented in Figure 3. These artificially prepared plasmas were studied in the same manner as fresh plasma to determine the effect of adding a serum-TP mixture. It will be observed that decreasing concentrations of prothrombin in plasma were associated with progressively prolonged coagulation times when the serum-TP mixture was added. This was particularly apparent after the serum-TP had been incubated for seven or 15 minutes. Ten per cent and 20 per cent plasma produced no coagulation after addition of the serum-TP mixture incubated for 15 minutes, whereas 100 per cent plasma was coagulated in 64 seconds by the same mixture. The bottom broken-line curve was obtained by activating serum obtained from a patient treated with dicumarol and then adding this serum-TP mixture to plasma containing 10 per cent prothrombin. The significance of this effect will be discussed later.

On the basis of the above experimental data it is felt that there is sufficient evidence to state that serum can be activated by thromboplastin to produce a "prothrombin-converting substance" which is then capable of causing conversion of prothrombin to thrombin in the virtual absence of ionized calcium. Fibrinogen cannot be converted to fibrin directly by the serum-activated substance. The minimal fibrin formation that does occur when serum-TP mixture is added to fibrinogen is probably related to small amounts of prothrombin contaminating the fibrinogen solution or to small quantities of thrombin or prothrombin residues contaminating the activated serum-TP mixture.

Activation of serum obtained from dicumarol-treated patients: It was found that serum from normal individuals, activated by thromboplastin and incubated as previously described, clotted plasma in a characteristic manner. Most sera from patients with various diseases showed little difference in this respect. In the presence of severe infections, however, a somewhat more flattened reaction curve was produced following thromboplastin activation. For example, the coagulation time of plasma after addition of a serum-TP mixture incubated for 15 minutes was 35 seconds in a typical case as compared with 55 seconds for nor-

² The preparations of fibrinogen and purified prothrombin used in these experiments was supplied through the generosity of Dr. W. H. Seegers, for which grateful acknowledgement is made.

mal serum. In these instances it was found that the plasma prothrombin concentration was diminished (Quick method [10]), and in the light of these observations a study was made of sera obtained from patients who were being treated with dicumarol.

The markedly changed pattern of reaction which follows activation of sera by thromboplastin from prothrombin-deficient patients, related to administration of dicumarol, is recorded in Figure 5. Serum D was obtained 12 hours after administration of 300 mg. of dicumarol *per os*, whereas sera C, B, and A, were obtained 36, 60 and 72 hours later. An analysis of the corresponding plasma revealed a reduction of prothrombin concentration from 100 per cent of normal to 33 per cent of normal (Quick's method).

It will be observed that the coagulation time of the serum-TP mixture, added to plasma after incubation for 15 minutes, is 10 seconds for serum B, in contrast to 60 seconds for serum D. Similarly, serum C, with an intermediate reduction of the corresponding plasma prothrombin concentration also showed an intermediate reduction of the plasma-serum-TP coagulation time (36 seconds) at the end of the 15 minute incubation period.

When such serial studies are made of patients who are receiving dicumarol, it is possible to show that there exists a fairly good correlation between the shape of the serum-activation curve and the concentration of prothrombin in the plasma. As the concentration of plasma prothrombin falls, a progressive shortening of the coagulation time of the serum-TP mixture develops when this is tested for coagulating effect on normal plasma after incubation for 15 minutes.

Figure 3, to which reference has previously been made, illustrates in another manner the enhanced effect obtained when serum from dicumarol-treated patients is activated by thromboplastin. It will be observed that coagulation of plasma containing 10 per cent concentration of prothrombin was more rapid, following addition of activated serum from a dicumarol-treated patient, than was coagulation of plasma containing 100 per cent prothrombin following addition of activated normal serum.

Serum from a dicumarol-treated patient was more susceptible of activation when smaller amounts of thromboplastin were utilized. This is clearly shown in Figure 6, where varying concentrations of thromboplastin were employed in activation of the normal serum and serum from dicumarol-treated patients. In this experiment 0.1 cc. of undiluted thromboplastin is designated "whole thromboplastin." Twofold dilutions of thromboplastin suspension were then made in 0.85 per cent sodium chloride solution and 0.1 cc. aliquots of the diluted suspensions were then added to 0.5 cc. amounts of serum to effect activation. The activation curves were then determined in the same manner as described in "methods." In Figure 6, the unbroken lines show results obtained when serum obtained from a dicumarol-treated patient was utilized. The plasma prothrombin concentration in this instance was 20 per cent of normal.

FIG. 5

Sera of patients receiving dicumarol were obtained at varying intervals following administration of 300 mg. of dicumarol. Serum D, whose corresponding plasma prothrombin concentration was 100 per cent of normal, was obtained 12 hours after dicumarol was given. Similarly, serum C (plasma prothrombin 63 per cent of normal) was obtained 36 hours after dicumarol; serum B (plasma prothrombin 42 per cent of normal) and serum A (plasma prothrombin 33 per cent of normal) were obtained 60 and 72 hours after dicumarol *per os*. The activated serum-thromboplastin mixture appears to have a more prolonged action as the corresponding plasma prothrombin concentration falls.

Effect of varying the concentration of thromboplastin added to serum to activate the coagulation factor. Respective dilutions of thromboplastin are indicated on the graph. One tenth cc. portions of these dilutions were added to serum. After the designated incubation periods (abscissa), 0.1 cc. amounts of this mixture were added to fresh oxalated plasma. There is a lessened coagulating effect when the amount of thromboplastin is decreased. The difference between activated serum from a patient treated with dicumarol (solid line) and normal serum (broken line) is again demonstrated.

The broken-line curves represent the results obtained after activation of serum from a normal individual whose plasma prothrombin concentration was 100 per cent of normal. These data show that serum obtained from the dicumarol-treated patient was much more effectively activated by thromboplastin than the sera of the normal individual.

It is evident that a striking difference exists between sera from fully dicumarolized patients and normal serum, following activation of these sera by thromboplastin. In fact, the data suggest that a converse relationship may exist between concentration of plasma prothrombin and the concentration of "prothrombin-converting factor" which can be activated from the corresponding serum.

As the plasma prothrombin concentration falls either more "prothrombin-converting factor" can be activated from the serum or the effect of the "prothrombin-converting factor" is more prolonged.

In view of the results obtained in a study of sera from patients treated with dicumarol, the results obtained in a study of a patient with severe cirrhosis of the liver associated with a prothrombin deficiency, are of particular interest. This patient with cirrhosis was found to have a plasma prothrombin concentration 40 per cent of normal (Quick's method [10]) associated with a coagulation time of 16 minutes (Lee-White method [11]). Vitamin K, administered parenterally, produced no change in the plasma prothrombin concentration. No disturbance of blood platelets or of any other coagulation factor was observed. Despite this, the patient developed severe epistaxis, purpuric skin lesions and at exitus he developed hemorrhage into the gastro-intestinal track. This patient's serum was studied on several occasions according to the method described. It showed a decreased ability to coagulate normal plasma after activation of the serum by thromboplastin as contrasted to normal serum. When serum from the patient with hepatic disease was compared with serum obtained from a patient receiving dicumarol with a reduction of prothrombin to a corresponding level, the difference in the two curves was quite evident. Several other patients with cirrhosis of the liver associated with decreased prothrombin have been studied in this manner. None of these patients had any hemorrhagic phenomena or disturbance of whole blood coagulation. In these patients, no results approximated those seen in sera of dicumarol-treated patients which had corresponding reductions of prothrombin. However, none showed any striking deviation of the reaction curve from that obtained following activation of normal serum and none showed such a striking deviation as the above patient with the prothrombin deficiency associated with disturbance of whole blood coagulation.

It is probable that the patient with hepatic disease associated with purpura, et cetera, had a deficiency of "prothrombin-converting factor" as well as prothrombin itself and that both defects may have contributed to the production of the ob-

served abnormality of coagulation and the purpuric manifestations.

Effect of addition of potassium oxalate to serum before and after thromboplastin activation: The preceding experiments have indicated that once activation of the "prothrombin-converting factor" has been accomplished, the reaction of prothrombin conversion can take place under conditions where the amount of ionized calcium is considerably reduced. When the concentration of oxalate in plasma is 0.01 M, coagulation by activated serum proceeds rapidly. If the molar concentration of plasma is increased to 0.02 M, the coagulation effect of activated serum is retarded and finally, no coagulation results if the concentration of oxalate in plasma is 0.04 M.

Furthermore, it was found that activation of serum by thromboplastin followed by addition of potassium oxalate, resulted in a rapid inhibition of coagulation activity of the serum-TP mixture. This loss of coagulation effect was observed even when the serum-TP mixture to which oxalate was added one minute later, was reacted with partially recalcified plasma. This plasma contained sufficient calcium more than to neutralize the amount of potassium oxalate added to the serum-TP mixture. It appears, therefore, that potassium oxalate

is able to reverse the active "prothrombin-converting factor" to an inactive form. This may represent the mechanism by which activated serum-TP mixtures are apparently inhibited in plasma containing high concentrations of potassium oxalate.

Table I demonstrates the effect obtained when potassium oxalate was added to serum *prior* to activation by thromboplastin. One-half cc. aliquots of normal human serum were added to 0.1 cc. amounts of a solution which contained varying concentrations of potassium oxalate. Several minutes later, 0.1 cc. of a thromboplastin suspension was added to the serum-oxalate mixture. Exactly one minute later, 0.1 cc. of the serum-TP-oxalate mixture was added to 0.1 cc. of 0.01 M oxalated plasma. It will be observed that coagulation of plasma resulted as long as the molar concentration of potassium oxalate was less than 0.0036 M. When the concentration of serum oxalate exceeded 0.0037 M, the activation of serum by thromboplastin was inhibited.

In order to eliminate the possibility that a cumulative concentration of potassium oxalate in the combined serum-TP and plasma might influence the speed of coagulation, the following control was made. The same series of serum-TP-oxalate mixtures was added to .005 M plasma. This plasma was prepared by adding 0.05 cc. of 0.1 M calcium chloride to 0.95 cc. of 0.01 M oxalated plasma. The amount of oxalate added to serum was more than neutralized by the concentration of calcium in the 0.005 M plasma. At the same time, plasma prepared in this manner did not spontaneously coagulate. It will be observed (Table I) that the coagulation effect of the serum-TP-oxalate mixture was not enhanced by use of partially recalcified plasma. In fact, the speed of coagulation was prolonged over that obtained in plasma which contained a higher concentration of potassium oxalate. The discrepancy of results obtained by use of 0.01 M and 0.005 M oxalated plasma is not clear, but it seems unlikely that any of the coagulation effect can be related to a direct action of thromboplastin *per se* on the plasma prothrombin.

These data are supportive evidence that prothrombin conversion can occur when the ionized calcium concentration is very low. The importance of calcium in coagulation seems to be re-

TABLE I

Effect of adding potassium oxalate to serum prior to activation by thromboplastin

* Concentration obtained by dividing molar concentration of potassium oxalate added by the dilution factor of serum and thromboplastin mixture, *i.e.*,

$$\frac{.02 \text{ M}}{7} \text{ oxalate} = .0028 \text{ M.}$$

† 0.005 M oxalated plasma was made by adding 0.05 cc. of 0.1 M CaCl₂ to 0.95 cc. of 0.01 M oxalated plasma.

Increasing concentrations of oxalate contained in 0.1 cc. were added to 0.5 cc. of serum. Following this, 0.1 cc. portions of thromboplastin suspension were added to the respective sera and one minute later, 0.1 cc. of this mixture was added to 0.1 cc. of 0.01 M or 0.005 M oxalated plasma. The coagulation time was then recorded.

lated to the stage of activation of "prothrombin-converting factor." In addition, once the "prothrombin-converting factor" has been activated, it can be rapidly inactivated if an excess of potassium oxalate is present in plasma or if potassium oxalate is added directly to the active serum-TP mixture.

Effects of physical agents on serum-thromboplastin activation: It has been shown that serum from normal individuals produces a characteristic predictable reaction curve following activation with thromboplastin (Figure 1). There is a release of "prothrombin-converting factor" followed by gradual decay of activity.

A progressive, slow loss of activatable "prothrombin-converting-factor" occurred when the serum was stored at 0° C. prior to addition of thromboplastin. A rapid loss occurred if serum was kept at 37° C., so that 10–12 hours later, only slight activation of the "prothrombin-converting factor" resulted after addition of thromboplastin.

FIG. 7

Effect of change of pH on restoration of activatable serum "prothrombin-converting factor." Ultra-violet irradiation of serum for two hours prior to activation by thromboplastin causes a marked decrease of activatable substance. After this serum was treated with alkali, followed by restoration of pH to 7.3, the activation curve approximates that obtained in the untreated serum.

When serum was irradiated by ultra-violet light, a rapid decrease of the "prothrombin-converting factor," capable of activation by thromboplastin, resulted.

Serum which becomes unreactive by aging or by ultra-violet irradiation can be almost completely restored to activity by treatment with dilute alkali or acid. In experiments illustrated in Figure 7, 0.25 cc. of 0.1 N NaOH was added to 0.5 cc. of inactive serum. Thirty minutes later 0.25 cc. of 0.1 N HCl was added to this mixture to restore the pH to a value between 7.0 and 8.0. When serum was treated in this manner, it was found to have nearly complete restoration of prothrombin-converting activity following addition of thromboplastin.

Storage of serum for as long as one year at refrigerator temperatures does not result in complete loss of the "prothrombin-converting factor." In fact, some of the sera which became alkaline (pH 8.5) after storage, were found to be capable of activation by thromboplastin without preliminary treatment with alkali or acid.

These data indicate that the "prothrombin-converting factor" of serum does not readily deteriorate, but only becomes reversibly inactivated.

Effect of crystalline soybean trypsin-inhibitor on activation of serum by thromboplastin: Since crystalline trypsin-inhibitor substances have been shown capable of delaying blood coagulation by inhibiting prothrombin conversion (12–14) a preparation of soybean trypsin-inhibitor³ was employed to study the effect of this substance by means of this experimental method. The preparation used in this protocol (Figure 8) produced appreciable prolongation of the plasma prothrombin time when 0.1 mg. was added to 0.1 cc. of plasma. Crystalline soybean trypsin-inhibitor was added in varying amounts to two different sera, one of which was obtained from a normal individual, while the other was obtained from a patient receiving dicumarol. The plasma, in the latter instance, was found to have a prothrombin concentration 28 per cent of normal. Examination of Figure 8 reveals that inhibition of activation of serum by thromboplastin was proportional to the amount of trypsin-inhibitor added to the serum. However, the de-

³ Crystalline soybean trypsin-inhibitor was supplied through the generosity of Armour and Company, Chemical Research Division, Chicago 9, Illinois.

FIG. 8

Soybean trypsin-inhibitor was added to serum (amount designated on the graph) prior to activation by thromboplastin. Two types of sera are shown, the solid lines representing normal sera, whereas the broken lines represent sera obtained from a dicumarol-treated patient. Trypsin-inhibitor reduces the activity of "prothrombin-converting factor," particularly after the serum-thromboplastin mixture with trypsin-inhibitor added has been incubated for seven minutes. In contrast, the "dicumarol serum" was less affected by the trypsin-inhibitor.

curve of the "prothrombin-converting factor" was affected less in the dicumarol than in the normal serum. For example, the serum-TP mixture, to which 0.2 mg. of trypsin-inhibitor had been added, was incubated for seven minutes and was found to produce coagulation of plasma in 200 seconds when normal serum was employed, in contrast to a coagulation time of plasma of 65 seconds when serum obtained from the patient treated with dicumarol was used.

Crystalline soybean trypsin-inhibitor was added to plasma in sufficient concentration to reproduce the amount which would be carried over in the above serum-TP mixtures. Serum was then activated by thromboplastin in the usual manner and added to the plasma-trypsin-inhibitor system. It was found that no inhibition of the activated "pro-

thrombin-converting factor" resulted. This observation indicates that soybean trypsin-inhibitor delays coagulation either by inhibition of thromboplastin or by inhibition of *activation* of the serum "prothrombin-converting factor."

DISCUSSION

When plasma coagulates, it is apparent that several constituents are either removed or destroyed as a result of the coagulation process. Prothrombin is removed by being converted to thrombin, which in turn is either destroyed or combined with other plasma components to form "metathrombin" (10). Fibrinogen is converted to fibrin which can then be removed as a clotted mesh. Serum, another end product of coagulation, contains, therefore, only small amounts of prothrombin and thrombin which deteriorate on standing and "metathrombin" which has been reported capable of reconversion to thrombin under suitable experimental conditions (15). At first it seemed logical to suppose that the coagulating effect of serum to which thromboplastin had been added was related to reconversion of "metathrombin" to thrombin. However, from the results of experiments with fibrinogen solutions and deprothrombinated plasmas it became apparent that the coagulating effect of activated serum could not be due to thrombin, but rather represented some factor which initiated coagulation through an intermediate action on prothrombin. It therefore seemed necessary to conclude that serum contains a "prothrombin-converting factor" which can be activated by thromboplastin. During the process of blood coagulation, the "prothrombin-converting factor" present in an inactive state *in vivo* in circulating plasma is activated either by thromboplastic globulin or tissue, or platelet thromboplastin to produce an active "prothrombin-converting factor" which in turn causes conversion of prothrombin to thrombin. Following the initial release of "prothrombin-converting factor" it is then converted to an inactive substance producing no effect on coagulation until more thromboplastin is added to reactivate it.

When serum is utilized to study the activation of the "prothrombin-converting factor" there is no substrate upon which this factor can effect a normal reactive process. It has been possible, therefore, to dissect the first stage of blood coagulation

and study this process more completely. By this method of study one can demonstrate a sudden release of "prothrombin-converting factor" soon after serum has been in contact with a suspension of thromboplastin. Following this, the "prothrombin-converting factor" slowly disappears from the serum-thromboplastin mixture. The degree of release of "prothrombin-converting factor" is directly related to the concentration of thromboplastin added to the serum for activation. Similarly, if one uses plasma which contains a reduced concentration of prothrombin, the clotting time will be correspondingly prolonged following addition of an active serum-TP mixture.

The mechanism by which the inactive serum "prothrombin-converting factor" is activated by thromboplastin is a topic for critical consideration. Ferguson (12), MacFarlane and Pilling (13), and Grob (14) have shown that serum and pancreatic trypsin-inhibitor substances have an appreciable influence on *in vitro* prothrombin conversion. It has been shown above that a crystalline soybean trypsin-inhibitor substance can appreciably alter the reaction curve when this is added to serum which is then activated by thromboplastin. Whether this effect is related to a neutralization of thromboplastin as MacFarlane and Pilling (13) believe, thereby diminishing the activating effect of the thromboplastin for serum, is not clear.

The type of reaction seen in the serum which has been aged or treated with ultra-violet irradiation may be related to a reversible denaturation of the reacting system, so that thromboplastin can no longer activate the "prothrombin-converting factor." When serum is treated by changing the pH, as described, then the "prothrombin-converting factor" again becomes capable of activation by thromboplastin in much the same manner as seen in fresh, normal serum.

On the basis of studies made on serum obtained from patients treated with dicumarol, it is apparent that there is a decided change produced in plasma, irrespective of the effect of dicumarol on the plasma prothrombin concentration. The data presented suggest that dicumarol administration is associated not only with a decreased concentration of prothrombin in the plasma, but also an increase of "prothrombin-converting factor." If this type of balance operates to preserve homeostasis of the coagulative mechanism, in that a reduction of pro-

thrombin would be counter-balanced by an increased concentration of "prothrombin-converting factor," then the enigma of marked prothrombin reduction without a profound disturbance of the coagulation mechanism might be more easily comprehended. A different and adverse situation appeared to be present in the patient with cirrhosis of the liver, who had a moderate reduction of prothrombin with associated hemorrhagic and coagulative disturbance, and at the same time was found to have a decrease in "prothrombin-converting factor."

One must consider furthermore that the altered reactivity of activated serum from dicumarol-treated patients might be associated with a decrease of inhibitor substance, thereby permitting a prolonged effect of the "prothrombin-converting factor."

On the basis of the experimental evidence presented, a revised formula of blood coagulation is suggested.

The validity of this equation might be strengthened if it could be determined whether thromboplastin is altered after it is added to serum. It has already been pointed out that thromboplastin remains unchanged if one attempts to determine the activity of thromboplastin by *in vitro* coagulation studies.

In vivo studies by Thomas (16) indicate that thromboplastin is changed when it is incubated with serum. He observed that thromboplastin injected intravenously into mice produced death by causing intra-vascular clotting. If thromboplastin was allowed to react with rabbit serum for several hours, many times a minimal lethal dose of thromboplastin could be injected intravenously without producing any adverse effect on the mice. Despite this, the "inactivated" thromboplastin had normal coagulative properties when *in vitro* studies were made. Thomas (16) treated thromboplastin with serum, following which he centrifuged the thromboplastin suspension free of the serum. When this

preparation was treated with potassium oxalate, it again became reactive to produce intra-vascular coagulation of blood. Similarly, he showed that thromboplastin was not inactivated by adding it to oxalated plasma and would continue to produce death in mice following intra-venous injection. These observations suggested to Thomas that a thromboplastin-inhibitory component of serum combined with thromboplastin in the presence of ionized calcium. This combination was easily dissociable if calcium ion was removed.

If these observations are applied to the equation suggested above to explain blood coagulation, it appears that the mode of activation of the "prothrombin-converting factor" might be related to a combination of thromboplastin with an inhibitor to release the "prothrombin-converting factor." It has been shown that such activation cannot take place unless ionized calcium is present.

It is much more difficult to explain how the serum-TP mixture finally becomes inert, only to be reactivated again by adding more thromboplastin or by adding more fresh serum.

No attempt has been made to correlate the above described "prothrombin-converting factor" with the chloroform-activated factor of serum and plasma, described by Tagnon *et al.* (17, 18). These workers have shown that treatment of serum or plasma with chloroform produces a substance which causes conversion of prothrombin to thrombin in the absence of ionized calcium. In addition, this factor causes lysis of fibrinogen and fibrin. When plasma was coagulated by a serum-TP mixture, according to the method described in this report, no lytic action of the serum-TP mixture was observed. However, Tagnon and co-workers have shown that thromboplastin and prothrombin inhibit the lytic action of the chloroform-activated factor.

It is possible that the chloroform-activated factor may be identical with the thromboplastin-activated factor described in the above experiments. Chloroform may cause a selective destruction of the inhibitor in the postulated "prothrombin-converting factor"-inhibitor complex, thereby permanently releasing a "prothrombin-converting factor."

SUMMARY

1. Preliminary investigations are reported which describe a method of activation of a pro-

thrombin-converting substance ("prothrombin-converting factor") by adding thromboplastin to serum. The activated "prothrombin-converting factor" causes conversion of prothrombin in the virtual absence of calcium; slowly decreases in activity following liberation from serum by thromboplastin; can be reactivated again by adding more thromboplastin to the inactive serum-thromboplastin mixture; and is unable to cause direct conversion of fibrinogen to fibrin.

2. Serum of dicumarol-treated patients, which is activated by thromboplastin, has a more sustained release of "prothrombin-converting factor." The activity of "prothrombin-converting factor," under these circumstances, increases as the level of plasma prothrombin falls. Conversely, a patient with cirrhosis of the liver, associated with an hemorrhagic disorder, was found to have a decrease of "prothrombin-converting factor" as well as a reduction of plasma prothrombin.

3. On the basis of the experimental evidence outlined, a revision of the generally accepted theory of blood coagulation is proposed.⁴

STUDIES IN IRON TRANSPORTATION AND METABOLISM. VII. EVIDENCE OBTAINED WITH RADIOACTIVE IRON THAT "EASILY SPLIT-OFF" BLOOD IRON IS AN ARTEFACT¹

BY MOISES GRINSTEIN AND CARL V. MOORE

(From the Department of Internal Medicine, Washington University, School of Medicine,
and the Barnes Hospital, Saint Louis, Missouri)

(Received for publication November 18, 1948)

Three different forms of blood iron have been described: hemoglobin iron, plasma (transport) iron, and "easily split-off" iron (E.S.Fe). The latter fraction, first studied by Barkan (1) and Lintzel (2), constitutes 5 to 10 per cent of the total blood iron. It derives its name from the fact that when blood is acidified and incubated with dilute hydrochloric acid the "easily split-off" fraction is ionized so that it can be separated from the remaining hemoglobin iron by dialysis or ultrafiltration. Lintzel and Radeff (3), and Legge and Lemberg (4) have demonstrated that E.S.Fe may be obtained in a similar manner from crystalline hemoglobin.

The amount of iron which can be "easily split off" from hemoglobin can be influenced in several ways. If blood or hemoglobin is treated with carbon monoxide, with reducing substances (*i.e.*, ascorbic acid, $\text{Na}_2\text{S}_2\text{O}_4$), or is evacuated of its oxygen prior to the addition of dilute hydrochloric acid, the ionization produced by the acid is reduced considerably (4-6). In addition, changes in the concentration of acid alter the size of the fraction (7-9). It is largest when the concentration of HCl is approximately 0.03 N and decreases progressively as the amount of acid is increased to about 0.6 N; further increases in HCl then cause comparatively little additional change. At concentrations of 0.1 N, nitric and sulfuric acids ionize nearly twice as much of the iron in red cells as does hydrochloric acid (7).

The nature and biologic significance of E.S.Fe blood iron have remained in doubt. Some workers have regarded the fraction as an artefact produced by the oxidation of the prosthetic group of the hemoglobin molecule by oxygen evolved when

acids are added to oxyhemoglobin. Barkan and Schales, however, presented evidence to show that E.S.Fe is derived from an intracorpuseular degradation product of hemoglobin, a bile pigment-iron-globin compound with an open porphyrin ring which they called pseudohemoglobin (6, 10).² This explanation was altered by Legge and Lemberg (4). After confirming the observation (6, 10), that about two-thirds of the E.S.Fe fraction was split-off only in the presence of oxygen and in the absence of reducing substances while the remaining third was ionized even in inert gases or CO, they concluded that the larger of these two fractions is an artefact while the smaller is at least partially attributable to a bile pigment-hemoglobin which gives rise to bile pigments when treated with acids. Even though these interpretations differ, both groups of investigators believe that at least a portion of E.S.Fe is derived from an intraerythrocytic pigment formed as one of the initial steps in the breakdown of hemoglobin to bilirubin.

On the other hand, the experiments with radioactive iron reported by Miller and Hahn (13) suggested that E.S.Fe is really an artefact. These observers administered radioactive iron to dogs and observed that several days later there was as much of the isotope present in the E.S.Fe of red blood cells as was found two weeks later. If all of the E.S.Fe is derived from a degradation pro-

² Pseudohemoglobin was prepared *in vitro* by Barkan and Schales by oxidizing oxyhemoglobin with hydrogen peroxide in the presence of cyanide (10). Legge and Lemberg (4), in many of their studies, used choleglobin prepared by coupled oxidation of hemoglobin and ascorbic acid (11). In both compounds, the $\alpha\text{-CH=}$ bridge of the heme molecule is open, and iron is readily dissociated by dilute acids. Both may be classified as verdohemoglobins. Liébecq regards them as being very similar, if not identical substances (12).

¹ These studies were supported by research grants established in memory of Philipp Hunkel and Nathan Greenberg.

FIG. 2. CONCENTRATION OF RADIOIRON APPEARING IN WHOLE BLOOD AND "EASILY SPLIT-OFF" BLOOD IRON OF A HEALTHY ADULT MAN AFTER INTRAVENOUS INJECTION OF Fe^{59}

5.6 mgm. of radioiron (Fe^{59}) having 7,200,000 counts per minute were given intravenously as ferrous ascorbate.

(See also explanations for Figure 1.)

FIG. 3. CONCENTRATION OF RADIOIRON APPEARING IN WHOLE BLOOD AND "EASILY SPLIT-OFF" BLOOD IRON OF A HEALTHY ADULT MAN AFTER INTRAVENOUS INJECTION OF Fe^{59}

5.6 mgm. of radioiron (Fe^{59}) having 7,200,000 counts per minute were given intravenously as ferrous ascorbate.

(See also explanations for Figure 1.)

* One-half the amount given on successive days.
† Days blood was kept refrigerated at 4° C. before determinations were made.

In neither instance was there any significant difference between the radioactivity per milligram of T.B.Fe and that per milligram of E.S.Fe. The greatest discrepancies appeared on days 24, 41, and 62 in Dog I. The significant fact, however, is that there was no tendency for the radioactivity in the E.S.Fe fraction to increase as the red cells containing the isotope grew older. In the legends to Figures 4 and 5 are tabulated representative blood counts obtained during the course of the experiment. From these data it is evident that the hemoglobin increased in each animal as it recovered from the anemia induced by hemorrhage. This increase in hemoglobin caused a dilution of the radioiron in the blood and accounts for the gradual decrease in the radioactivity per milligram Fe in both the T.B.Fe and E.S.Fe.

In Dog III, a hemorrhagic anemia was also induced. This animal was followed for only 22 days after he had been given radioiron orally; E.S.Fe was determined after blood had been saturated with CO. The counts per minute per milligram of iron in the T.B.Fe fraction agreed very well with the activity in the fraction separated after exposure to CO (Table II).

TABLE II

Comparison between the concentration of radioactive iron in whole blood and in the "easily split-off" blood iron fraction, determined after saturation with carbon monoxide
Dog III

Days after oral administration	Total blood Fe			"Easily split-off" Fe determined after saturation with carbon monoxide		
	Radioactivity			Radioactivity		
	mgm./100 ml. blood	ct./min./100 ml. blood	ct./min./mgm. Fe	mgm./100 ml. blood	ct./min./100 ml. blood	ct./min./mgm. Fe
8	42.65	512,500	12,000	0.94	11,370	12,100
22	44.60	524,000	11,750	1.06	12,080	11,400

The animal had been made anemic by repeated bleeding prior to administration of radioiron. 47.6 mgm. of radioactive iron (Fe⁵⁵ and Fe⁵⁹) were given by stomach tube, as ferric chloride. Total counts = 11,900,000/min.

III. Human subject with hypochromic anemia

A study similar to that described in the two previous sections was made on a woman, S. W., 35 years of age, with a severe degree of hypochromic anemia (Figure 6). In this instance, the radioiron was given orally. The absorbed isotope

FIG. 4. CONCENTRATION OF RADIOIRON APPEARING IN WHOLE BLOOD AND "EASILY SPLIT-OFF" BLOOD IRON OF A DOG MADE ANEMIC BY INDUCED HEMORRHAGE

17.4 mgm. of radioiron (mixture of Fe^{55} and Fe^{59}) were given intravenously as ferric chloride. Total counts = 7,200,000/min.

Day	R.B.C.	Hb.	C.V.
1	3.26	6.5	22.5
11	5.48	10.3	35.5
41	6.22	14.4	46.0

145	7.20	15.9	49.5

(See also explanations for Figure 1.)

FIG. 5. CONCENTRATION OF RADIOIRON APPEARING IN WHOLE BLOOD AND "EASILY SPLIT-OFF" BLOOD IRON OF A DOG MADE ANEMIC BY INDUCED HEMORRHAGE

34.8 mgm. of radioiron (mixture of Fe^{55} and Fe^{59}) were given intravenously as ferric chloride. Total counts = 14,400,000/min.

Day	R.B.C.	Hb.	C.V.
1	3.41	6.5	23
11	5.21	10.2	35.5
41	6.8	15.0	46
90	7.35	15.6	47
145	6.9	18.4	50

(See also explanations for Figure 1.)

FIG. 6. APPEARANCE OF RADIOIRON IN THE WHOLE BLOOD AND "EASILY SPLIT-OFF" BLOOD IRON FRACTION OF A PATIENT WITH HYPOCHROMIC ANEMIA

55 mgm. of radioiron (mixture of Fe^{55} and Fe^{59}) given orally as ferrous chloride. Total counts = 32,000,000/min. Patient was treated with 2.4 gm. of ferrous gluconate daily after the 16th day.

Day	R.B.C.	Hb.	C.V.
1	4.41	8.6	28
16	4.11	8.7	27.5
42	5.11	10.1	35
71	4.37	12.4	38
144	3.82	10.1	32

(See also explanations for Figure 1.)

was utilized promptly for hemoglobin synthesis, but by the time observations were discontinued on the 144th day the amount of radioiron in her peripheral blood had decreased to approximately one-third of the peak value. This fall was unquestionably caused by menorrhagia with the loss of large amounts of blood.

As in the normal subjects and in the dogs, the radioactivity per milligram of iron in both T.B.Fe and E.S.Fe remained almost identical during the whole period of study.

IV. Patients with Addisonian pernicious anemia

In order to study the differences which might occur in the radioactivity present in T.B.Fe and E.S.Fe during the first few days after administration of the isotope, it was necessary to select subjects who were manufacturing hemoglobin at an accelerated rate. This precaution was required to make certain that the amount of radioiron pres-

ent in the fractions during the first few days would be large enough to count. Accordingly, radioiron was given intravenously to three patients with Addisonian pernicious anemia during the period of accelerated erythropoiesis following the institution of specific therapy. The results for two of these observations are charted in Figures 7 and 8. Utilization of the injected isotope was prompt and approximately complete. In the first subject (O. A. W., Figure 7) more radioactivity was discovered during the first two days per milligram of iron in the E.S.Fe fraction than in the T.B.Fe. As will be emphasized later, this increase was probably due to the radioactive iron remaining in the plasma. After the first 48 hours, the radioactivity per milligram of iron in E.S.Fe remained slightly but consistently lower than in T.B.Fe.

Determinations of E.S.Fe after blood had been saturated with carbon monoxide were made on the second patient (J. M., Figure 8). This patient was the only one of all the subjects studied in

FIG. 7. APPEARANCE OF RADIOIRON IN THE WHOLE BLOOD AND "EASILY SPLIT-OFF" BLOOD IRON FRACTION OF A PATIENT WITH PERNICIOUS ANEMIA DURING RESPONSE TO LIVER EXTRACT

Liver extract in therapeutic doses had been given approximately two weeks prior to the injection of radioiron. 6.5 mgm. Fe^{59} as ferrous ascorbate injected intravenously. Total counts: 10,980,000.

10	3.77	11.3	35.5

(See also explanations for Figure 1.)

FIG. 8. APPEARANCE OF RADIOIRON IN THE WHOLE BLOOD AND "EASILY SPLIT-OFF" BLOOD IRON FRACTION OF A PATIENT WITH PERNICIOUS ANEMIA DURING RESPONSE TO VITAMIN B_{12}

Three weeks prior to the radioiron 46 μg . of Vitamin B_{12} had been given intramuscularly. Five mgm. of Fe^{59} as ferrous ascorbate injected intravenously. Total counts: 2,840,000. Red blood cell values were increasing rapidly at the time the iron was administered.

(See also explanations for Figure 1.)

whom the radioactivity per milligram Fe of E.S.Fe differed significantly from that in T.B.Fe. It was consistently lower during the 48 days of observation; further study became impossible when the patient left the hospital. The reason for this different result is not clear. That it was not due to the fact that determinations were done in CO was demonstrated on the 32nd and 48th days when E.S.Fe was measured in the usual manner (Table I); a similar lower activity was found.

The radioiron in plasma during the first 48 hours after injection of radioactive ferrous ascorbate was followed in the third subject (W.S., Table III).

TABLE III

Radioactive Fe in the plasma of a patient with pernicious anemia (W. S.) during first 48 hours after intravenous injection of Fe⁵⁹

Time following radioiron I.V. hours	Counts/min./100 ml. plasma
15	6380
24	3120
48	880

Five mgm. Fe⁵⁹ given I.V. as ferrous ascorbate 21 days after initiation of liver therapy. Red blood cell values were rising rapidly during the time these observations were made. Total counts administered = 7,900,000.

It can be seen that relatively large amounts of radioactivity were present in the plasma during this period. Since the plasma iron is also ionized by the concentrations of acid used for determination of E.S.Fe, the radioactivity in this latter fraction would tend to be falsely high during the first several days after injection of radioactive iron. This fact probably accounts for the high concentrations of Fe⁵⁹ in the E.S.Fe fraction observed at 24 and 48 hours in O. A. W. (Figure 7).

V. Effect of storing blood

If hemoglobin transformation to bilirubin begins within the red blood cell by formation of a verdohemoglobin, then it is possible that the intracorpuseular degradation of hemoglobin would take place more rapidly in stored blood. Should this occur in blood which contains hemoglobin tagged with Fe⁵⁹, one would expect that the radioactivity per milligram of iron would progressively increase in the E.S.Fe fraction. To test this possibility, blood obtained from F. M., an adult male with malignant hypertension, was collected on the seventh day following the first of two injections

of tagged ferrous ascorbate. As described in the Methods Section, the blood was stored in small flasks at 4° C. On the second, 20th, and 28th days, flasks were removed for analysis. While there was a tendency for the total amount of iron in the E.S.Fe fraction to increase, particularly when CO was used to saturate the blood, there was no appreciable change in the radioactivity per milligram of iron (Table I). Observations had to be terminated after 28 days because the cells became hemolyzed.

DISCUSSION

In all observations except those made on one of the patients with pernicious anemia (J. M., Figure 8), there was extremely close correlation between the radioactivity per milligram of iron in whole blood and that in the "easily split-off" fraction. Radioiron appeared just as promptly in the E.S.Fe fraction as in the T.B.Fe. There was, furthermore, no tendency for the concentration of radioactivity in the E.S.Fe to increase as erythrocytes aged and reached the end of their life span, as would be expected if E.S.Fe bore any relationship to the formation of an intracorpuseular degradation product of hemoglobin. The same type of result was obtained whether E.S.Fe was determined on oxygenated blood or on blood which had been saturated with carbon monoxide prior to the addition of acid. The data indicate that "easily split-off" blood iron as defined by Barkan is an artefact and originates entirely or almost entirely from intact hemoglobin.

These observations do not, however, eliminate the possibility that a small fraction of E.S.Fe may originate from an intraerythrocytic verdohemoglobin like choleglobin or pseudohemoglobin. It is conceivable that the methods used were not delicate enough to detect the small increase in concentration of radioiron which would occur in E.S.Fe under these circumstances as the cells aged. That such a possibility exists, is suggested by Lemberg's and Legge's (17) demonstration that: (1) normal human red blood cells contain 1 to 5 µg. of biliverdin combined as choleglobin per milliliter of cells; and (2) the injection of phenylhydrazine into rabbits causes an increase in the choleglobin of their erythrocytes. Gardikas, Keuch and Wilkinson (18), however, have recently criti-

cized the technique used by Lemberg and Legge on the grounds that choleglobin might well have been formed during their determinations. Gardikas *et al.* repeated the observations under anaerobic conditions and failed to detect choleglobin in 12 separate samples of blood. Furthermore, except in one instance each of leukemia, pernicious anemia, and obstructive jaundice, they failed to demonstrate the pigment in blood taken from patients with pernicious anemia, leukemia, hemolytic anemias, polycythemia, or hepatic and obstructive jaundice. At the present time, therefore, there remains no unchallenged demonstration that any pigment formed as a degradation product of hemoglobin regularly occurs within red blood cells. There is no convincing evidence that the transition of hemoglobin to bilirubin begins as an intraerythrocytic process. It is emphasized that even if such a pigment were found to be present, it would account for only a small fraction of E.S.Fe and would not seriously affect the conclusion that the E.S.Fe fraction is an artefact.

SUMMARY AND CONCLUSIONS

At intervals following the administration of radioactive iron to normal human subjects, to patients with hypochromic and pernicious anemias, and to dogs made anemic by repeated bleeding, the concentration of radioactive iron in the total blood iron and in "easily split-off" iron was measured. In some of the observations "easily split-off" iron was determined on samples of blood which had been saturated with carbon monoxide prior to the addition of acid. In one experiment, citrated blood was stored at 4° C. and determinations were made at intervals for 28 days. Radioactivity appeared in the "easily split-off" blood iron fraction just as promptly and in the same concentration as it appeared in hemoglobin. No correlation was noted between the radioactivity in the "easily split-off" iron fraction and ageing of the red blood cells. It is concluded that "easily split-off" blood iron, whether determined on oxygenated blood or on blood saturated with carbon monoxide, is an artefact. The possibility exists that a small fraction of the "easily split-off" iron may be derived from intraerythrocytic verdohemoglobin, but no convincing evidence exists for the presence in red

cells of such a pigment nor for the belief that degradation of hemoglobin begins within the erythrocyte.

A COMPARISON OF THE DIRECT FICK AND THE GROLLMAN METHODS FOR DETERMINATION OF THE CARDIAC OUTPUT IN MAN

BY LARS WERKÖ, STIG BERSEUS, AND HENRIK LAGERLÖF

(From the IVth Medical Service, St. Eriks Hospital, and the Medical Department, the Serafiner Hospital, Stockholm, Sweden)

(Received for publication September 14, 1948)

The introduction of the cardiac catheter by Forssman (1) and its later development as a useful physiological instrument by Cournand (2, 3) have made possible the determination of the cardiac output by the direct Fick principle in man (4). Using this method, a number of investigators have reported values of 5.5 to 6.5 liters per minute for the basal cardiac output, which correspond to 3.1 to 3.8 liters per minute per square meter of body surface area (3, 5-8). These values are higher than those obtained earlier with the Grollman acetylene inhalation method or the Krogh-Lindhard nitrogen oxide method (3.9 liters per minute) (9-12). The arteriovenous oxygen difference, determined according to the Fick method, has been found to be 40 to 45 cc. per liter of blood, as compared with 60 cc. per liter of blood using the acetylene method. This discrepancy has been discussed at length. It has been suggested by those working with the gas inhalation methods, that the heart catheterization procedure so disturbs the subject, that basal values cannot be secured. Different investigators using the catheter technique have obtained the same values in similar series, without an increase in oxygen consumption, heart rate or blood pressure (3), and have pointed out that these values have all varied consistently from those obtained by the Grollman technique.

The purpose of the work described in this study was to determine the cardiac output simultaneously by both methods and to account for any differences noted.

MATERIAL AND METHOD

Medical students, nurses or patients with minor cardiovascular diseases were used as subjects.

The subjects were trained for the Grollman technique the day before the study. The heart catheterization was done according to earlier descriptions (3, 8). The sample of mixed venous blood was always taken from the

pulmonary artery and the arterial blood from the brachial artery. The first cardiac output was determined according to the Fick principle after the heart catheter and the arterial needle had been in place for at least 30 minutes.

Immediately after the first Fick determination, the acetylene rebreathing was performed. The first sample of alveolar air was taken 17 to 18 seconds and the second 26 to 27 seconds after the start of rebreathing acetylene (10, 11, 13, 14). Twenty to 30 minutes later the same procedure was repeated. Twenty to 30 minutes later a third Grollman determination was done.

Twenty minutes later a single blood sample was drawn from the pulmonary artery. Immediately afterward a rebreathing according to Grollman but without acetylene was performed. Another blood sample from the pulmonary artery was drawn between 17 and 27 seconds after the start of rebreathing. These samples were analyzed for oxygen content on the Van Slyke apparatus in order to establish the influence of the rebreathing procedure on the mixed venous blood and the arteriovenous oxygen difference.

In three subjects the effect of recirculation was studied. Blood was drawn in five second periods from the pulmonary artery, during the rebreathing of acetylene. The blood was analyzed for acetylene content of the Van Slyke volumetric apparatus. In each subject two to three experiments were done. It was usually possible to obtain blood during two five second periods at each experiment, for example, between five to 10 and between 15 to 20 seconds after the start of acetylene breathing.

RESULTS

In Table I the age of the subject, diagnosis, oxygen consumption, and the arteriovenous oxygen difference obtained with the two methods are tabulated. The values for arteriovenous oxygen difference using the acetylene method were always larger than those obtained according to the direct Fick method. The difference varied between 5 and 49 cc. per liter with a mean of 26.5 ± 2.79 and was not proportional to the value given by the Fick method. The third determination of arteriovenous oxygen difference in each subject was done after allowing a 20 minute interval between the two methods. If these are excluded, the dif-

TABLE I

Patient Age Sex	Diagnosis	O ₂ -consumption	B.M.R.	Arteriovenous O ₂ -difference		
				Catheter method	Grollman method	Difference Grollman- Catheter

Mean:				35.0	61.5	26.5 ± 2.79 N = 22

ference will be the same, or 26.5 ± 3.51 cc. per liter. This value is significant. The determination of arteriovenous oxygen difference according to the direct Fick principle thus gives values about .45 per cent lower than with the acetylene method.

In order to analyze the experimental errors involved, the following procedure was adopted:

The experimental error was defined as the variability of a single determination (δ_x) and calculated in two different ways:

The differences between determination 2 and 1, or 3 and 2, were computed for each method separately.

The differences 2 to 1 and 3 to 2 were of the same order of magnitude; thus all differences constituted a single group of data.

As the mean differences were not significant, the variability of a single determination may be calculated ac-

cording to the following formula:

$$\delta_x = \frac{1}{\sqrt{2}} \cdot \delta_d \quad (15)$$

where

δ_x = variability of single determination
 δ_d = standard deviation of difference

The results are given in Table II. The greatest differences between the determinations of the catheter method were -14 and +9, corresponding to an experimental error of 9.9 per cent (Table II). The value of -14 was found in patient No. 7, with basal metabolic rate of +40 per cent. This value falls outside the normal range of variation. If it is excluded the experimental error (Table II) will decrease to 5.6 per cent.

The experimental error was then calculated by a combination of analysis of variance (16), using Snedecor F-ratio as test of significance (17), dif-

TABLE II

*Experimental error of the catheter and Grollman method
(calculated per differences)*

(a) Catheter method

No. of diff.	Mean	Mean differences $D \pm \epsilon_D$	Stand. deviation of diff. (δ_d)	Exp. error (δ_x)	
1	2	3	4	5	6
15	35.0	0.67 ± 1.26	ml. 4.88	ml. 3.46	per cent of mean 9.9
14	35.6	1.70 ± 0.75	2.81	1.99	5.6

(b) Grollman method

1	2	3	4	5	6
15	61.5	3.53 ± 4.39	17.0	12.1	21.3

ferentiating between the variation between individuals (δ_i) and within individual (δ_x) the latter corresponding to the experimental error, and "classical analysis."

The results are given in Table III.

TABLE III

*Experimental error of the catheter and the Grollman method
(calculated by analysis variance)*

	No. of indiv.	No. of determ.	Variability			
			Between individuals (δ_i)		Within individuals exp. error (δ_x)	
			ml.	per cent of mean	ml.	per cent of mean
Catheter	8	23	10.3	29.7	3.53	10.2
Grollman	8	23	15.3	24.4	13.3	21.2

The agreement between the two methods of calculation was excellent.

The catheter method was thus found to have a coefficient of variation for a single determination of 10 per cent (5.6 per cent), whereas the acetylene method, applied on the same patients under the same conditions during the simultaneous catheterization had a coefficient of variation of 21 per cent, which is significantly higher. The variability between the patients was found to be about the same for both methods (30, or 24 per cent).

There was no difference in oxygen content of the blood in the pulmonary artery sampled before, or 17 to 27 seconds after, the start of rebreathing. In eight cases the maximal difference between

the samples was 0.2 volumes per cent, the oxygen content being higher in some cases and lower in others during rebreathing.

The test for recirculation of acetylene showed that between five and 10 seconds after the start of acetylene breathing there was no acetylene in the pulmonary artery blood. However, in 10 to 15 seconds acetylene was present in the pulmonary artery blood, in amounts corresponding to an acetylene content in the alveolar air of 0.4 to 0.5 volumes per cent. In 15 to 20 seconds, this amount corresponded to approximately 1.5 volumes per cent.

DISCUSSION

In almost simultaneous determinations there was a statistically significant difference in arteriovenous difference and cardiac output of 45 per cent between values obtained with the direct Fick and the acetylene methods. This confirms earlier work in which separate determinations were done using these two methods. Bauman and Grollman have previously reported values with the acetylene method and the direct Fick that agreed fairly well (18). The mixed venous blood in their cases was sampled after puncture of the heart and the sampling done immediately after the rebreathing of acetylene, both factors making the results uncertain. The belief that the discrepancy between values for cardiac output obtained with heart catheterization and with the acetylene technique is due to apprehension produced by the catheterization is disproved by the result of this study. Instead, the difference must be due to some systematic error in the acetylene method.

Gladstone believed that the rebreathing technique augmented the circulation and thus gave rise to errors (9). The present study conclusively shows that there is no difference in oxygen content in the mixed venous blood during the short time of rebreathing as compared to that before rebreathing.

Hamilton, Spradlin and Saam, working with dogs, have shown (19) that the recirculation of acetylene is too rapid to permit waiting 25 seconds before the second air sample is taken. Rapid recirculation was confirmed by Starr and Collins, who used the dye injection technique in dogs (20).

Grollman and Bauman, on the contrary, after heart puncture in man, found that significant amounts of acetylene did not appear in the blood in the right ventricle until 25 seconds after the start of acetylene breathing (18). Hohwü Christensen was able to demonstrate that the acetylene content in the peripheral venous blood was very low and rose slowly, due to the diffusion of acetylene from the blood to the tissues (21, 22).

The present study shows that significant amounts of acetylene appear in the pulmonary artery blood between 10 and 15 seconds after the start of acetylene breathing. Since it is impossible to get full mixing and equalization of the acetylene within this time, it may be assumed that these factors are inherent sources of error in all methods using inhalation of foreign gas. This error becomes greater the longer the time elapsing before the second sample is taken. That recirculation is the main source of error is also shown by the fact that, in patients with slow circulation, *e.g.*, cardiac failure, gas inhalation methods give values for arteriovenous oxygen difference that equal those obtained with the direct Fick principle, 90 to 100 cc. per liter of blood (3, 13, 23). The results of dye injection experiments in man with the dye injected in the pulmonary artery and the right auricle also show that there is a significant recirculation within 10 seconds (24).

SUMMARY AND CONCLUSIONS

1. Almost simultaneous determinations of cardiac output according to the direct Fick (after heart catheterization) and the acetylene methods were made in eight subjects. A total of 22 sets of determinations were made.

2. There was a statistically significant discrepancy in the values obtained by the two methods for the AV oxygen difference. The mean difference averaged 26.5 ± 2.79 cc. per liter; the Fick method giving values about 45 per cent lower than the Grollman.

3. The experimental error for the Fick method was 5.6 per cent and for the acetylene method, 21 per cent.

4. The rebreathing procedure did not change the oxygen content in the pulmonary artery blood during the 27 seconds that the rebreathing lasted.

5. Tests for recirculation showed that within 10 to 15 seconds after the start of acetylene breathing

significant amounts of acetylene were found in the pulmonary artery blood.

6. Any method using inhalation of foreign gas will give values for arteriovenous oxygen difference which are too large, if the gas sampling is not completed before 10 to 15 seconds after the start of rebreathing. This error is not constant but, due to the speed of the circulation, is small or absent with slow circulation and is large with rapid circulation.

A FACTOR DETERMINING THE LOCATION OF PSEUDOFRACTURES IN OSTEOMALACIA

BY M. LE MAY¹ AND J. W. BLUNT, JR.

*(From the Departments of Radiology and Surgery, College of Physicians and Surgeons,
Columbia University, and the Radiological and Surgical Services,
The Presbyterian Hospital, New York)*

(Received for publication October 11, 1948)

Narrow bands of diminished density, which resemble fracture lines and often appear symmetrically and last for months to years, have been described in the skeletons of individuals with a variety of diseases. The purpose of this paper is to offer a rational explanation for the bizarre locations of these pseudofractures as they occur in osteomalacia and to focus attention upon a possible mechanism for their occurrence.

The numerous descriptions of this phenomenon and the speculations as to its causes have been reviewed by Camp and McCullough (1). It has been described as a radiological syndrome by Milkman (2, 3). Histologically, such lesions in cases of rickets and osteomalacia were found by Looser (4, 5) to consist of infractions of the bones with subsequent laying down of non-calcified callus. Since they are not true fractures with complete separation of bone continuity, he called them *umbauzonen*, zones of alteration. He concluded that mechanical tension on softened bone, such as that due to muscle strain, perhaps caused small breaks in the cortex with gradual infractions through the rest of the bone, thus producing the long-lasting, symmetrical lines of diminished density resembling fracture lines. Callus about true fractures remains uncalcified for a long time in cases of osteomalacia, and Looser felt that it was not strange for these *umbauzonen* to persist for a considerable time after their first appearance.

Albright and coworkers (6) have reviewed the cases in which pseudofractures have been found. They state that the narrow decalcified bands which occur in otherwise normal-appearing bone, and which tend to be symmetrical and remain stationary for months to years, occur only in osteomalacia or rickets. They point out that the underlying bone disturbance in the variety of conditions where

these bands of diminished density have been noted, *i.e.*, rickets, late rickets, celiac disease, chronic idiopathic steatorrhea, sprue, and severe acidosis, is really osteomalacia. The lesions are common in advanced cases of hunger osteopathy. Somewhat similar bands occur in Paget's disease, congenital syphilis, marble bones, osteogenesis imperfecta and hyperparathyroidism, but in these conditions the lesions are rarely symmetrical and occur through areas of definite bone abnormality as seen by X-ray. "March fractures" appear in otherwise normal bones but are rarely symmetrical and readily unite and become calcified. As for the mechanism of production of pseudofractures,

FIG. 1. SCAPULA SHOWING PSEUDOFRACTURE

¹ Present address: Argonne National Laboratory, Chicago, Illinois.

Albright and coworkers refer to the work of Looser (4).

During the past year on the Radiological service of the Presbyterian Hospital, we have seen four patients with these narrow bands of lessened density. They all showed blood findings consistent with osteomalacia, *i.e.*, normal calcium, low phosphorus and elevated alkaline phosphatase. One was a case of long-standing osteomalacia of undetermined origin; the other three showed the syndrome, described by Albright and coworkers (6), of renal acidosis without nitrogen retention. Pseudofractures occurred in similar locations in the bones of these four individuals. As in the published cases, the most common sites for these lesions were in the axillary border of the scapula (Figure 1), the ribs, the pubic rami, and the upper end of the femur. They also occur in the iliac bones (Figure 2), and near the base of the spine of the scapula (Figure 3).

FIG. 2. ILIUM AND THE NECK OF A FEMUR SHOWING PSEUDOFRACTURES

FIG. 3. PSEUDOFRACTURE OCCURRING IN THE SPINE OF A SCAPULA. A SYMMETRICAL LESION IS PRESENT IN THE OPPOSITE SCAPULA

The pseudofractures in the scapulae and the iliac bones, particularly, occur in areas where muscle strain seems unlikely. Since these lesions tend to develop regularly in the same places in different patients and tend to be symmetrical on the two sides of the body, an anatomical explanation for the lesions was sought.

CLINICAL MATERIAL AND METHOD

Complete skeletal radiographs were made of the four patients mentioned above. The reproductions of radiographs in cases reported in previous studies (2, 3, 6-11) were reviewed and in 28 of these cases the illustrations were adequate to show accurate localization of the lesions. Dissection was made of the blood vessels supplying the trunks and extremities of three cadavers to ascertain the proximity of the main vessels to the bones.

RESULTS

The sites where pseudofractures have been found, and the arteries which commonly cross the bones at these sites, are shown in the two halves of Figure 4. The number of times lesions were found

FIG. 4. SKELETON SHOWING THE USUAL SITES OF OCCURRENCE OF PSEUDOFRACTURES AND THE ARTERIES WHICH COURSE THE BONES AT THESE SITES

The figures signify the number of lesions found at these locations in four cases at the Presbyterian Hospital and the lesions pictured in previous studies (2, 3, 6-11).

at these sites in our four cases and in which they were adequately pictured in the cases reported previously is indicated on the figure. The arteries shown are those coursing directly over the bones at the sites of the lesions as given in standard anatomy works (12, 13). All of these arteries were found by dissection to lie in contact with the bone. The blood vessels in the hands and feet vary considerably in different individuals in relation to the bones and therefore were not included in the figure.

DISCUSSION

Pseudofractures are not infrequent in the first rib where the bone is normally notched by the subclavian artery. In the axillary border of the scapula where the circumflex scapular artery grooves the bone, 13 pseudofractures were found. A detailed view of the blood vessels around the scapula is shown in Figure 5, and the close correspondence between the locations of these blood vessels and the scapular lesions shown in Figure 4 will be noted. A pseudofracture has also been described (3) in the outer end of the acromion at the site of the vessel shown in Figure 5.

Careful positioning of the patient is required at times to demonstrate some of the pseudofractures, particularly those in the ribs and scapulae. To be seen clearly, small incomplete fractures in normal bone due to trauma also require careful positioning of the patient. Both types of lesions are more distinct when they occur perpendicular to the long axis of the trabecular pattern of the bone. This could explain the failure of lesions to be common where the radial artery spirals the humerus. We have seen only one case (14), that of a severe rachitic infant, with bilateral symmetrical spiral lesions in the midportion of the humerus. Gross examination of normal scapulae shows that some of them are not grooved by the circumflex scapular artery. Variation in the course of this blood vessel may explain why pseudofractures are not

FIG. 5. SCAPULA SHOWING THE POSITION OF THE BLOOD VESSELS IN RELATION TO THE BONE

always seen at this site. Similar variations of other blood vessels may produce the individual differences observed. The lesions in ribs nine, 10, 11, and 12, and the posterior lesion in rib six could be at the site of branches of intercostal arteries. Vessels were found in these areas in one of three cadavers examined.

Mechanical stress, such as that due to muscular or postural strain, may produce true fractures at the site of pseudofractures, particularly in the upper end of the femurs in the far advanced cases. It seems doubtful that this type of strain would account for most of the lesions initially. Fractures from other mechanical causes do not often occur at the sites commonly affected in osteomalacia, as demonstrated in Cushing's disease by the fractures in the anterior ends of the lower ribs where respiratory strain on the thoracic cage is greatest. The true fractures, and even some of the pseudofractures, occurring in cases of osteomalacia may be due to other kinds of mechanical stress, but most of the lesions are at sites where muscular or postural stress is unlikely, and where arteries lie in close contact with the bones. The most likely explanation for the occurrence of these lesions here would be some type of vascular stress.

Normal bone tends to yield to continuous pressure in a very definite way as is clearly demonstrated in the skull by patterned thinning due to the pressure of convolutions of the brain and in other bones by grooving due to pressure of blood vessels. Although the exact mechanism of bone erosion at sites of pressure is not known, it is not surprising that malacic bones should respond differently to stress than normal bones. Small breaks in the cortex of bones at the site of mechanical stress due to pulsating blood vessels, rather than muscular strain as suggested by Looser, would be followed by the laying down of callus. As osteomalacia is characterized by failure of deposition of calcium in newly formed osteoid tissue, the callus would remain uncalcified in these sites and account for the radiological and pathological appearance of the pseudofractures. That there is selective resorption, or lack of deposition of calcium adjacent to the large blood vessels, seems less likely. It is to be hoped that the correlation between the locations of blood vessels and sites of pseudofractures given here will initiate attempts at pathological or operative verification, and experi-

mental study of the mechanism of this phenomenon in osteomalacia and possibly other bone diseases.

The pressure of vessels upon the bones may also account for some of the similar bands of decreased density occasionally appearing in the skeletons of patients with other conditions, such as osteogenesis imperfecta, marble bones, and Paget's disease, but these lesions occur in abnormal bone, as seen by X-ray, and their mechanism and character would vary with the disease and especially with the ability to calcify the callus formed.

SUMMARY

The location of the narrow bands of diminished density which often appear symmetrically and last for months to years in the skeletons of patients with osteomalacia, is shown to correspond with the location of main blood vessels which lie on the bones. It is suggested that the mechanical stress caused by the vessels may result in small breaks in the cortex with subsequent laying down of callus which, in osteomalacia, is uncalcified. This mechanism explains the symmetrical appearance of the pseudofractures in otherwise normal appearing bone and their location at sites not usually subjected to other mechanical stresses.

THE OXYGEN CONSUMPTION OF THE NORMAL AND THE DISEASED HUMAN KIDNEY¹

By WALTER H. CARGILL² AND JOHN B. HICKAM

(From the Department of Medicine, Duke University School of Medicine, Durham, N. C.)

(Received for publication October 18, 1948)

The development of a technique of intravenous catheterization and its application to the sampling of renal venous blood (1) have made possible the study of the metabolic activity of the kidney in the unanesthetized human subject. We have used this method of investigation in conjunction with the usual clearance procedures in an attempt to determine the oxygen consumption of the normal kidney and its variation in disease.

METHODS

All subjects were studied at rest and in the post-absorptive state. Inulin and sodium para-aminohippurate (PAH) clearances were performed as described by Goldring and Chasis (2), urine being collected by bladder catheterization. Following the injection of the priming doses and the starting of the sustaining infusion of inulin and PAH, a modified ureteral catheter was introduced into an antecubital vein of the opposite arm, and passed under fluoroscopic visualization through the right atrium and inferior vena cava and into the right renal vein. The rotation of the curved tip of the catheter posteriorly, and other details of technique have been described by Bradley (3), and by Warren, Brannon, and Merrill (1). Urine was collected at accurately timed intervals of 10-30 minutes, and at approximately the midpoint of each urine collection period blood samples were obtained from a femoral artery and the right renal vein. There was usually an interval of one or two minutes between the withdrawal of these samples. A portion of each sample was collected anaerobically, either under mineral oil, or in an oiled heparinized or citrated syringe, and the oxygen content determined by the method of Van Slyke and Neill (4). The remainder of the samples were oxalated and centrifuged as soon as possible for the determination of the plasma inulin and PAH content by the methods of Corcoran and Page (5) and Smith *et al.* (6). From two to six urine collection periods and a corresponding number of pairs of arterial and renal venous blood samples were obtained from each subject. In addition, paired samples of heparinized and oxalated whole blood were obtained from each subject for hematocrit and oxygen capacity determinations.

² Present address: Department of Medicine, Emory University School of Medicine, Atlanta, Georgia.

Clearances of inulin and PAH were calculated in the usual manner from the rate of urinary excretion and the arterial levels of these substances. The percentage extraction of PAH was determined by the formula $\frac{A-R}{A} \times 100$, where A and R represent the PAH concentrations in arterial and renal venous plasma, respectively, and the renal plasma flow obtained by dividing the clearance of PAH by the extraction: $RPF = \frac{C_{PAH}}{\text{Ext. PAH}}$. A discussion of the calculation of renal plasma flow in this manner is presented in a separate publication (7). This figure was corrected for the hematocrit reading to obtain the renal blood flow. The difference in oxygen content between arterial and renal venous blood (renal oxygen extraction), expressed as volume of O₂ per cc., was multiplied by the renal blood flow to obtain the renal oxygen consumption: Renal oxygen consumption = RBF × A_{O₂} - R_{O₂}.

Van Slyke *et al.* (8) have maintained that the arterial-renal venous oxygen difference is not always a true measure of renal oxygen extraction in the dog, since they found definite differences in the hemoglobin content (oxygen capacity) of arterial and renal venous blood in that animal. In 22 comparisons of the oxygen capacities of paired arterial and renal venous samples we have found a mean difference of 0.2 volume per cent, with a standard error of $\pm .01$. Seventy-one comparisons of paired arterial and renal venous hematocrit determinations showed a mean difference of 0.1 per cent packed red cell volume, with a standard error of .07. These differences are well within the limits of technical error.

Since the arterial-renal venous oxygen difference is quite small, and must be multiplied by a large figure for renal blood flow to obtain the oxygen consumption, the measurement of this difference constitutes a potential source of grave error. All oxygen determinations were done in duplicate and discarded if they did not agree within 0.1 volume per cent. Successive samples of arterial and renal venous blood in a given patient over a one or two hour period usually showed minor fluctuations in oxygen content, the mean difference between successive determinations of A-V differences in 31 subjects being 0.05 volume per cent. It is felt that these variations are partly real and partly due to technical error; in any case, they are not of sufficient magnitude to compromise the conclusions we have drawn from our observations.

All figures have been corrected to a standard surface area of 1.73 sq. m.

RESULTS

Thirty-six subjects have been studied in this manner. (Additional studies on most of these subjects have been presented in a separate publication [7]). For the presentation of the data they have been divided into four groups, according to the clinical classification of their disease. The first group (Table I) consists of ten patients in whom no organic disease could be demonstrated or who were suffering from a chronic illness unrelated to the kidney. The clinical impression of normal renal function in these subjects was confirmed by the demonstration of normal values for glomerular filtration rate and renal blood flow as established by others. The renal oxygen extraction (arterial-renal venous oxygen difference) is extremely small in comparison with arterio-venous differences elsewhere in the body, ranging from 1.09 to 1.87 volumes per cent, with a mean value of 1.42 volumes per cent. Although the amount of oxygen removed from each unit of blood perfusing the kidney is quite small, the renal blood flow is so large that the total renal oxygen consumption is of considerable magnitude, ranging from 12.0 to 20.8 cc./min., with a mean value of 16.0 cc./min.

The second group of subjects consists of patients whose predominant complaint was hypertension, and in whom a history of previous renal disease could not be elicited. In some of them renal damage was clinically demonstrable, as evidenced by albuminuria, reduced phenolsulfonthalein excretion, or hyposthenuria. On purely clinical grounds it was presumed that the impaired renal

function in these subjects was secondary to the hypertension, and that the diagnosis of nephrosclerosis was applicable. It will be seen from Table II that the renal blood flow varied in this group from normal to extremely low levels. The oxygen extractions did not vary correspondingly, the mean, 1.51 volumes per cent, being not significantly different from the normal mean.

The six subjects listed under Table III as chronic nephritis were patients who gave histories of long-standing kidney disease and who were found to have severe impairment of renal function. Of these, N. W. and L. H. probably represented chronic pyelonephritis, the others chronic glomerulonephritis, although the clinical differentiation of these diseases was open to question. In spite of the marked reduction in renal blood flow in this group, to a mean value of 353 cc./min., the renal oxygen extractions were within the normal range.

Significant clinical data on ten patients who were diagnosed as acute or subacute glomerulonephritis are summarized in Table IV. Two of these patients (G. W. and G. I.) were obviously in the nephrotic or "degenerative" stage of the disease, as demonstrated by massive edema, proteinuria and extreme hypoalbuminemia and hypercholesterolemia. In the others, hypertension, hematuria, or a combination of all elements of the disease predominated. W. A. had an attack of hemorrhagic nephritis of several weeks' duration two years preceding the time of study. He had been asymptomatic until one week before admission when he suffered a mild upper respiratory infection, and puffiness of the eyelids and microscopic hematuria were noted. It is felt that he represents an acute exacerbation of a latent glomerulonephritis. The clinical course of patient R. E. was more suggestive of essential hypertension than glomerulonephritis; he was placed in

this group because of albuminuria, hematuria, and the discovery of red blood cell casts in his urinary sediment. It is our impression that these findings do not accompany primary hypertension except in the malignant phase.

A consistent finding in all of these patients was a greater reduction in glomerular filtration rate than in renal blood flow, so that the filtration fraction was uniformly low. This is suggestive of primary glomerular disease, and is in keeping with the findings of Earle, Taggart, and Shannon (8). Likewise, the normal values for renal blood flow indicate that the disease process was not of long standing.

It may be seen from Table V that the renal oxygen consumption of these patients varied between extreme limits, from 0.9 cc./min. to 13.8 cc./min. Since the blood flows were normal or only slightly reduced, this variation was due almost entirely to changes in oxygen extraction. This is in con-

trast to the preceding groups, in which variations in blood flow and normal oxygen extractions were found. No correlation existed between the predominant symptomatology in any patient and the oxygen consumption of his kidneys. It is true

that patient D. R., whose renal oxygen consumption was extremely low, was also the most severely ill; patient B. B., however, whose kidneys were also consuming comparatively little oxygen, was ambulatory at the time of study. Although the

oxygen data in two of these subjects were normal, we consider it noteworthy that the mean values for both oxygen extraction and renal oxygen consumption for the entire group are distinctly below the normal range.

The data may be represented graphically as in Figure 1, where renal blood flow is plotted against oxygen consumption. The scatter in the normal range is large, but it is clearly evident that as the renal blood flow falls in chronic renal disease there is a corresponding fall in renal oxygen consumption. In contrast, the majority of the patients with acute and subacute glomerulonephritis are distinguished by a low oxygen consumption with a normal renal blood flow. This difference disappears when oxygen consumption is plotted against glomerular filtration rate, as in Figure 2. Although there is no apparent relation between these factors in any one group, a definite correlation ($r = .76$) exists when all 36 subjects are considered.

DISCUSSION

The rate of oxygen utilization by an organ is generally considered to be an expression of its metabolic activity. The metabolism of the normal mammalian kidney has been the subject of numerous investigations (9-12), all of which have demonstrated that renal oxygen consumption is quite high in relation to the weight of the organ, and that this high oxygen consumption is the result of a small arterio-venous oxygen difference (oxygen extraction), and a large renal blood flow.

Van Slyke *et al.* (9) and others (11, 12) have observed in the dog that renal oxygen extraction

remains constant when renal blood flow is varied, so that the rate of oxygen consumption is a function of blood flow. Similar results have been obtained in man by Bradley and Halperin (13), who used the technique of intravenous catheterization to determine renal oxygen consumption before and during reduction of renal blood flow by abdominal compression. These authors also observed that the reduced oxygen consumption found during the period of decreased blood flow was associated with apparent cessation of urine formation in a certain proportion of nephrons, and suggested the possibility that "renal oxygen consumption depends upon the relative proportion of tubular tissue actively functioning in the formation of urine from glomerular filtrate."

In this view, it seems logical to expect that renal oxygen consumption would vary with filtration rate if the amount of functioning tubular tissue remained unchanged. Our data show that the kidneys of patients with acute and subacute glomerulonephritis, which had low rates of glomerular filtration, also had low rates of oxygen utilization, in spite of normal or increased blood flow. Earle, Taggart, and Shannon (8) have shown that although the total amount of functioning tubular tissue (as estimated from diodrast Tm) tends to fall with the filtration rate, the ratio of filtration rate to Tm is lower than normal in the early stages of glomerulonephritis, so that there is a greater depression of filtration than of tubular function. It is conceivable that the observed reduction in renal oxygen consumption in our patients was due to decreased formation of glomerular filtrate. An alternative explanation is that in acute and subacute glomerulonephritis there is a fundamental alteration in the metabolic activities of renal cells which results in a diminished utilization of oxygen.

It is of interest in this connection that we have found a definite correlation between filtration rate and oxygen consumption in all our subjects (Figure 2).

The progressive vascular occlusion and destruction of renal parenchyma which result in the granular, contracted kidneys of nephrosclerosis and chronic nephritis are accompanied by decreases in both blood flow and oxygen consumption (Figure 1). It is probable that the diminished oxygen consumption found in these patients is simply a reflection of the lowered metabolic demands of the

functionally smaller kidneys, the volume of blood flow being an expression of the amount of surviving tissue.

Merrill (14) has found that the decreased renal blood flow accompanying congestive heart failure is compensated for by an increased oxygen extraction, so that oxygen consumption remains normal. (We have found extractions of 3.6 and 4.2 volumes per cent, values significantly greater than our normal mean, in two subjects with congestive failure who are not included in the present series.) Glomerular filtration rate was also reduced in these patients. If filtration rate determines tubular work, and therefore renal oxygen consumption, it is necessary to suppose that independent tubular activity is increased in congestive heart failure.

Although the kidneys of the patients with acute and subacute glomerulonephritis were consuming comparatively little oxygen, they were carrying on all of the functions which are generally considered to constitute renal work, including the reabsorption of water and electrolytes against osmotic gradients, the excretion of urea, and the tubular secretion of PAH. The disproportion between the oxygen consumption of the kidney and the theoretical thermodynamic requirements of known renal work has been pointed out by Barcroft and Brodie (10), Glaser *et al.* (11), and Van Slyke *et al.* (9). These last investigators concluded that "the overwhelmingly greater part of the energy produced must be utilized by the kidney for its own internal cellular processes not related to the external work which the organ is performing." Since the nature of these internal cellular processes is completely obscure, it is not inconceivable that their activity, and consequently the demand of the kidney for oxygen, may vary within wide limits without being detectable by known methods of measurement.

In view of the extensive speculation concerning the relation of renal ischemia to essential hypertension our observations in patients with this disease are of interest. Pathologists agree that longstanding hypertensive disease is usually associated with progressive narrowing and even occlusion of small renal blood vessels, particularly the preglomerular arterioles. The functional counterpart of this constriction of the renal vascular bed is evident in some of our patients, in whom definite reductions of renal blood flow were found.

Since the decreased blood flow was not accompanied by an increased oxygen extraction, the oxygen consumption of these kidneys was also low.

The question of whether these vascular changes precede or follow the hypertension has been the subject of much debate. In four patients with sustained hypertension of at least six months' duration we have found normal values for renal blood flow and oxygen consumption, which demonstrates that in at least some cases of essential hypertension the metabolic activities of the kidney are carried on at the normal level.

SUMMARY AND CONCLUSIONS

1. Renal oxygen consumption in unanesthetized human subjects has been estimated by combining the techniques of intravenous catheterization and sodium para-aminohippurate clearance.
2. The mean normal renal oxygen extraction was found to be 1.42 volumes per cent, and the mean normal renal oxygen consumption 16.0 cc./min.
3. Decreased levels of oxygen consumption were found in patients with nephrosclerosis, chronic glomerulonephritis, and chronic pyelonephritis, who also had diminished renal blood flow. Oxygen extraction was normal in these patients.
4. In patients with acute and subacute glomerulonephritis the extraction of oxygen was decreased in spite of a normal or increased renal blood flow.

THE MEASUREMENT OF GLOMERULAR AND TUBULAR PLASMA FLOW IN THE NORMAL AND DISEASED HUMAN KIDNEY¹

By WALTER H. CARGILL²

(From the Department of Medicine, Duke University School of Medicine, Durham, N. C.)

(Received for publication October 18, 1948)

The clearance of para-aminohippuric acid (PAH) has been extensively used as a measure of the rate of renal plasma flow. The validity of this measurement depends upon the assumption that at low plasma levels PAH is completely extracted from the blood by tubular cells, and that therefore the only limiting factor to its rate of excretion in the urine is the rate at which it is delivered to the tubules. There is ample proof that this assumption is justified in normal man under basal conditions (1, 2). However, in any condition in which the total number or the functional capacity of tubular cells is decreased, the complete extraction of PAH and therefore the use of the clearance alone as a measure of renal plasma flow is open to serious question. The uncertainty as to the degree of renal impairment which is compatible with complete extraction of PAH has hampered the application of this method to the study of the diseased human kidney.

According to the Fick principle, the blood flow through an organ may be determined if the rate of consumption (or excretion) of a substance and the concentration of this substance in blood entering and leaving the organ (arterial-venous difference) are known. The application of the technique of venous catheterization to the sampling of blood from the renal vein in man (1) has made possible the utilization of this principle to determine the actual renal blood flow under conditions in which the extraction of PAH may not be completed.

In the normal kidney histological studies indicate that under most circumstances the blood flow through the tubules equals the blood flow through the glomeruli. In the diseased kidney either the glomeruli or tubules may be destroyed separately and there is no assurance from

histologic studies that glomerular flow equals tubular flow. The glomerular flow can be measured from the rate of inulin excretion and the arterio-renal venous difference of inulin and compared with the tubular flow measured at the same time by the PAH excretion and arterio-renal venous PAH difference.

METHODS

The standard clearance procedures described by Goldring and Chasis (3) have been followed. Priming and sustaining infusions of inulin and sodium para-aminohippurate were given and urine collected by bladder catheterization at accurately timed intervals of 10-30 minutes. The dosage of PAH was adjusted to achieve an arterial blood level between 1 and 3 mg. per cent. An intravenous catheter was introduced into the right renal vein according to the procedure described by Warren, Brannon and Merrill (1). At approximately the midpoint of each urine collection period samples of renal venous and femoral arterial blood were withdrawn. The inulin and PAH content of plasma and urine were determined by the methods of Corcoran and Page (4) and Smith *et al.* (5), corrections being made for inulin blanks in plasma and urine. A 1:5 cadmium sulfate filtrate was used for PAH determinations in renal venous plasma instead of the 1:15 filtrate for arterial plasma. Paired samples of heparinized blood were obtained from each patient for hematocrit determinations.

CALCULATIONS

The application of the Fick principle to the determination of renal plasma flow in the dog from the excretion and extraction of PAH has been discussed by Phillips *et al.* (6). As we have not found any significant difference between arterial and renal venous hematocrit readings, nor between the PAH concentration of whole blood and plasma, we have not applied the corrections these authors suggest, but have used simply the formula (1)

$$RPF = \frac{UV}{A - R}$$
where UV is the rate of urinary excretion of PAH (mg./min.), and A and R represent the PAH concentrations in arterial and renal venous plasma (mg./cc.). The extraction of PAH was determined as the quotient of the arterial-renal venous PAH difference

and the arterial level: (2) $Ext. = \frac{A - R}{A}$, and multiplied by 100 to express it as a percentage. The clearance

¹ Aided by a grant from the Life Insurance Medical Research Fund.

² Present address: Department of Medicine, Emory University School of Medicine, Atlanta, Ga.

of PAH was calculated in the usual manner from the rate of urinary excretion and the arterial level: (3)

$$C_{PAH} = \frac{UV}{A}. \text{ It is evident from the integration of equations (1), (2) and (3) that the renal plasma flow may be obtained by dividing the clearance of PAH by its extraction: (4) } RPF = \frac{UV}{A - R} = \frac{C_{PAH}}{\text{Ext. PAH}}.$$

Since inulin is a foreign substance which is neither metabolized nor stored by the kidney, substitution of inulin concentrations in the above formulae should also yield a valid estimate of renal plasma flow. According to the available evidence, inulin is excreted entirely by glomerular filtration, whereas the excretion of PAH is accomplished largely by active tubular transfer. The value for renal plasma flow obtained from inulin concentrations should represent therefore only the volume of plasma which perfuses the glomeruli and, derived from PAH clearance and extraction, the flow through both glomeruli and tubules, predominantly the latter. These determinations may therefore be designated glomerular plasma flow (GPF) and tubular plasma flow (TPF).

The filtration fraction (FF) represents the fraction of plasma water which is filtered at the glomerulus, and has been determined by us as the ratio of the inulin clearance to the tubular plasma flow: $FF = \frac{C_{IN}}{TPF}$. If glomerular and tubular plasma flows are equal, the filtration fraction should equal the inulin extraction as obtained from Equation (2).

This derivation of the filtration fraction differs from that usually given, as other investigators have used this term to represent the ratio of the inulin clearance to the PAH clearance alone. Our values for FF are therefore lower than those previously reported.

All figures have been corrected to a surface area of 1.73 sq. m.

RESULTS

Data on ten subjects who were hospitalized for minor illnesses unrelated to the kidney, and

who had normal blood pressures, are summarized in Table I. The subjects with abnormal renal function have been divided into two groups: those in whom vascular changes might be considered primary, and those in whom disturbances of renal circulation might be considered secondary to glomerular dysfunction. The first group (Table II) includes patients whose predominant complaint was high blood pressure. In some of these impairment of renal function was manifested clinically by albuminuria, hyposthenuria, and decreased phenolsulfonphthalein excretion. Others presented only a history of elevated blood pressure for six months or more. Two patients who were diagnosed clinically as chronic pyelonephritis are also included in this group.

The second group (Table III) is composed entirely of subjects with acute, subacute or chronic glomerulonephritis.

There are many possible objections to this division of subjects. The variety of structural changes which may be produced in the kidney by any one of these disease processes is reflected in the disagreement of authorities as to their pathological classification. The existence of diffuse arteriolar disease in chronic glomerulonephritis is well recognized, as is the fact that extensive glomerular changes occur in nephrosclerosis. A functional basis for the clinical classification of these patients is revealed, however, in the values found for the filtration fraction. As demonstrated in Figure 1, there is a sharp division between the patients with hypertensive disease of the kidney and those with glomerulonephritis; the former lying above, and

the latter below the normal mean. The two patients with chronic pyelonephritis were found to have filtration fractions similar to the patients with nephrosclerosis with comparable degrees of renal damage.

It may be seen from Tables II and III that the extraction of PAH remains within the normal range (83-93 per cent) until renal damage is moderately advanced. The number of determinations is insufficient to allow quantitative assessment of the degree of renal impairment which is incompatible with the complete extraction of PAH at low plasma levels. It appears, however, from these data that PAH extraction does not begin to decrease until the inulin clearance has fallen below

60 cc./min. and PAH clearance below 300 cc./min. Figure 2 is a graphic representation of the latter relationship.

Estimates of glomerular and tubular plasma flow, as determined from the clearance and extraction of inulin and PAH, are given in the tables and compared in Figure 3. The correlation between the two determinations in individual patients is often poor (particularly in patients D. R. and A. J.), but in general the ratio of the values approaches unity. Less divergence is found when mean values are considered. For all 28 patients in whom comparisons were made, the mean rate of glomerular plasma flow was 497 cc./min., and the mean rate of tubular plasma flow 466 cc./min.

FIG. 1. FILTRATION FRACTION VALUES IN PATIENTS WITH HYPERTENSIVE DISEASE OF KIDNEY AND WITH GLOMERULONEPHRITIS

We consider this convergence of the means to indicate that the individual differences are random and probably not significant, although the heterogeneity of the sample does not permit statistical analysis.

We have found greater fluctuations in the inulin concentrations of successive samples of renal venous blood than in the corresponding arterial samples. This phenomenon is being investigated further, as we feel that it may indicate some intermittency of glomerular filtration.

DISCUSSION

The application of clearance and saturation methods to the study of diseased kidneys has yielded much valuable information. Characteristic functional patterns in various renal disorders have been described (7, 8), involving chiefly alterations in the ratio of glomerular filtration to the mass of actively functioning tubular tissue. Less is known concerning disturbances of renal circulation in abnormal human kidneys, for the reasons set forth in the introduction to this article.

FIG. 2. PAH EXTRACTION AND PAH CLEARANCE IN NORMAL SUBJECTS AND IN PATIENTS WITH HYPERTENSION, GLOMERULONEPHRITIS AND CHRONIC PYELONEPHRITIS

The present investigation has been concerned with the determination of cortical blood flow from the excretion and extraction of inulin and PAH. On theoretical grounds, agreement might be expected in normal subjects between the values ob-

FIG. 3. GLOMERULAR AND TUBULAR PLASMA FLOW DETERMINATIONS IN NORMAL SUBJECTS AND IN PATIENTS WITH HYPERTENSION, GLOMERULONEPHRITIS AND CHRONIC PYELONEPHRITIS

tained by using these two compounds. White and Heinbecker (9) found in the dog that determinations of renal plasma flow from the clearance and extraction of inulin and diodrast differed by less than 10 per cent. Reubi (10), however, has recently claimed that in man estimations of plasma flow from mannitol and PAH clearance and extraction do not agree. Our data show essential agreement between inulin and PAH determinations of plasma flow in seven subjects with normal renal function.

The morphologic studies of Dehoff (11) and of Oliver (12) indicate that an extensive reorganization of the vascular pattern of the cortex takes place in the late stages of both nephrosclerosis and glomerulonephritis. Whereas in the normal kidney the tubules are supplied only with post-glomerular blood, in the diseased kidney numerous channels are to be found through which blood may pass directly from an interlobular artery or afferent arteriole to a peritubular capillary. The development of these vascular short-circuits has been associated by Oliver with the loss of the normal functional predominance of the glomerulus and the appearance of relatively aglomerular tubules. Smith (13) has postulated the existence of "impotent nephrons" lacking tubular activity, through which glomerular filtrate may pass unchanged to collecting ducts.

It is conceivable that an extensive disturbance in the balance between glomerular and tubular blood supply might be reflected in a disproportion between the rates of plasma flow as estimated from inulin and from PAH excretion and extraction (GPF and TPF). We have not found such a disproportion, even in severely diseased kidneys. It is true, of course, that the methods employed yield only an estimate of the total blood supply of all functioning glomeruli and tubules, and it is manifestly impossible to detect from our data any dissociation of flow between the parts of individual nephrons. The results show only that the overall rates of perfusion of glomerular and tubular tissue are similar. This is not necessarily an index of the relative size or spatial relation of these segments. Smith (13) has pointed out that the circulation of interstitial fluid in the kidney makes possible the extraction of diodrast by tubular cells located at a distance from the glomerulus where the filtration of inulin took place. It is probable

that the values we have found in abnormal kidneys represent the means of a variety of rates of flow corresponding to the areas of atrophy and hypertrophy which figure so prominently in microscopic sections of the diseased cortex. The absence of an appreciable difference between rates of plasma flow as determined by inulin and by PAH makes it highly unlikely, however, that the adaptive and regressive changes described by Oliver are associated with any significant redistribution of the blood supply between glomerular and tubular tissue. The only alternative is to assume that in the kidneys under discussion inulin may be excreted by tubular cells or that PAH is excreted entirely by glomerular filtration. The different degrees of clearance and extraction of these substances make either of these possibilities highly unlikely.

Raaschou (14) has pointed out that in diseased kidneys the filtration fraction as calculated from clearances alone is an artificial concept, meaning only the relation between the volume of filtered fluid in the glomeruli and the amount of plasma flowing past active secretory tissue. The same objection might be raised to the use of the ratio of filtration rate to the minimal renal plasma flow as determined from PAH clearance and extraction. Since, however, the filtration fraction so derived equalled the observed extraction of inulin, we feel that it is a valid concept even in diseased kidneys, representing the actual fraction of plasma water filtered at the glomeruli.

A low filtration fraction in the early and moderately advanced stages of glomerulonephritis has been noted previously by other workers (7, 8, 15). We have found that the filtration fraction remains low even in the late stages of this disease. This finding emphasizes the predominantly glomerular localization of the morbid process throughout its course, and suggests that the decreased circulation found late in the disease is secondary to glomerular obliteration. In the acute and subacute stages of glomerulonephritis, particularly in the nephrotic stage, a low filtration rate may be the only functional abnormality noted. A few of these patients actually showed an increased renal blood flow as measured both by inulin and by PAH.

In contrast is the elevation of the filtration fraction in patients with hypertension and hypertensive disease. Here the abnormality is primarily vascu-

lar in origin. Smith and his associates believe that the maintenance of the filtration rate with a decrease in blood flow is due to functional constriction of the efferent glomerular arteriole. Our observations suggest that the filtration fraction tends to fall as the vascular disease progresses. This fall may represent the addition of occlusive changes in the afferent arteriole which counteract the efferent vasoconstriction and lower the intraglomerular pressure.

The recent demonstration by Trueta *et al.* (16) of arterio-venous shunts in the rabbit kidney has given rise to much speculation as to the existence and importance of these shunts in man. If blood is shunted away from the cortex through juxta-medullary channels the extraction of PAH should fall. This has been found to happen in rabbits (17). Our data indicate that in the diverse conditions studied PAH extraction was not decreased until renal damage was moderately advanced, suggesting that the Trueta mechanism is not operative in the early stages of hypertension and glomerulonephritis under resting conditions.

SUMMARY AND CONCLUSIONS

1. Glomerular plasma flow (GPF) has been estimated from the rate of urinary excretion and the arterial-renal-venous inulin difference, and compared with the tubular plasma flow (TPF) obtained from the excretion and renal extraction of sodium para-aminohippurate in normal subjects and in patients with varying degrees of renal impairment.

2. The general agreement between the values obtained for GPF and TPF indicates that there is no extensive dissociation of glomerular and tubular circulation, even in advanced renal disease.

3. The ratio of glomerular filtration rate to renal plasma flow (filtration fraction) is lower than the normal mean in all stages of glomerulonephritis, and higher than normal in nephrosclerosis and chronic pyelonephritis.

HYPERVOLEMIC ANEMIA IN CIRRHOSIS

BY JEANNE C. BATEMAN, HAROLD M. SHORR, AND TORBJORN ELGVIN

(From the Department of Medicine, New York University College of Medicine, and the Third Medical Division of Bellevue Hospital, New York City)

(Received for publication August 9, 1948)

Anemia is usually considered to exist when there is a reduction of hemoglobin, red blood cells or both, per unit volume of blood. This concept is valid in most types of anemia. There is an apparent tendency on the part of the body to compensate for a reduction in circulating red cell mass by an increase in plasma with resultant more or less normal blood volume for the individual (1). We have found this to be true even with the profound reduction of red blood cell mass occurring in cases of aplastic anemia of unknown etiology. There are, however, certain exceptions wherein gross alterations in total blood volume may mask the true hematological state. Reduction in total blood volume in spite of increase in plasma volume has been reported in pernicious anemia during relapse (2-4). Conversely, a significant increase in total blood volume with a relatively greater increase in plasma volume than in circulating red cell mass may, when only routine blood counts are done, suggest a more severe grade of anemia than actually exists. Such cases might be expected to respond poorly to hematinic agents. The following data suggest that the anemia occurring in cirrhosis of the liver is of this character.

METHODS

Hemoglobin determinations were done by the oxy-hemoglobin method on a Klett Summerson photoelectric colorimeter. Normal hemoglobin values for males were considered to be 16 grams per cent, for females 14 grams per cent. The Nesslerization method was employed for plasma protein determinations and readings were made on a Coleman Junior spectrophotometer. Plasma volume was measured by the Evans Blue (T-1824) dye method using a single blood sample as recommended by Gregersen (5). The plasma dye concentration was determined on a Coleman Junior spectrophotometer. The standard curve was made with plasma. Blood for hematocrit determination was drawn from the antecubital vein following release of the tourniquet. In a small series of simultaneous hematocrit determinations on blood drawn in this manner and femoral vein blood there was found to be no essential difference. Heparin was used as an anticoagulant

and hematocrit readings were made after 30 minutes of centrifugation at 3000 r.p.m. Gibson (6) using radioactive iron found the body hematocrit to be about nine-tenths of the large vessel hematocrit. This suggests that hematocrit determinations done in the usual way may be too high. Total blood volume was calculated from plasma volume and hematocrit according to the formula:

$$\frac{\text{Plasma vol. in cc.}}{100 - \text{hematocrit}} \times 100 = \text{Total blood volume}$$

Results of total blood volume determinations done on four healthy young male adults ranging from 174 to 180 cm. in height were found to be 5,051, 5,277, 5,500 and 5,532 cc. These figures are slightly lower than those of Gibson (7) for normal individuals of this height. The calculated normal values for blood and plasma volumes of the patients studied were derived from the chart prepared by Gibson and Evans (7) using the patient's height as the basis of the calculation. It has been suggested that in the presence of obesity or significant weight loss, height or ideal weight be employed to predict normal plasma volume (8).

The figures for hemoglobin and red blood counts corrected for expected normal blood volumes were derived by the following formula:

$$\frac{\text{Patient's hemoglobin}}{\text{Estimated normal blood volume}} \times \text{Blood volume calculated by dye hematocrit method} = \text{Corrected hemoglobin}$$
$$\frac{\text{Patient's red blood count}}{\text{Estimated normal blood volume}} \times \text{Blood volume calculated by dye hematocrit method} = \text{Corrected red blood count}$$

Bone marrow for study was obtained by sternal puncture done under local anesthesia. The relationship between the sternal marrow findings and the peripheral blood counts is depicted on Figure 1.

MATERIAL

Seven cases of cirrhosis of the liver from the Third Medical Division of Bellevue Hospital were studied. The hematological observations on these patients were made prior to and during the administration of therapy for cirrhosis as well as for the anemia which the patients exhibited. The studies were terminated by transfer to another hospital (one case), by death (two cases), and arbitrarily when it became obvious that the patient had not responded to hematinic agents in the expected fashion

(three cases). One patient in whom the diagnosis was not clear cut (M. F.) ran an unexpected course.

The data on these cases are summarized in Table I. There are four males and three females ranging from 36 to 58 years of age. All patients but one had histories of excessive alcohol consumption with more than one previous hospital admission for that complaint alone. One male had a history of inadequately treated lues and the female with no history of alcoholism was found to have positive serology on two occasions. The symptoms included weakness of varying duration in all patients and weight loss which was frequently partially masked by ascites formation. Complaints referable to the abdomen were those of vague abdominal discomfort usually promptly followed by the development of swelling. Gastro-intestinal complaints consisted of anorexia in six individuals, bouts of nausea and vomiting in four. Hemorrhagic phenomena had been present at some time in four patients although in the 36 year old male these could be attributed to a concurrent vitamin C deficiency.

Dullness or confusion was present in four patients, milder personality abnormalities in two. Only the non-alcoholic patient showed no signs of mental deterioration. Telangiectasia was present in five cases, hepatomegaly in all, splenomegaly was noticed in only one, jaundice (usually mild or moderate) was present five times, and ascites and edema six times.

Laboratory data are given in the table. Only representative determinations are presented. One patient (M. F.) whose history and physical findings were somewhat atypical was found to have esophageal varices on X-ray as well as biopsy findings compatible with cirrhosis. The diagnosis of cirrhosis was substantiated in two other patients by biopsy studies.

Sternal marrow studies (Figure 1) failed to reveal a megaloblastic bone marrow even in R. G. whose mean corpuscular volume was 126 and who showed a moderately severe grade of anemia. One patient, V. D., who was almost terminal at the time of study manifested a marked depression in the red cell series. No striking abnormalities were noticed, otherwise.

The hematological studies in relationship to blood volume and therapy are presented graphically in Figures 2 to 7 inclusive. No blood volume studies were done on T. M. (Figure 2) but his lack of response to hematinic drugs was characteristic even of patients treated longer and more vigorously. The slight reticulocyte rise observed following institution of therapy was considerably below that which might be expected in an anemia of the degree suggested by his blood counts.

Two patients (V. D. and E. F.) expired shortly after admission to the hospital. It was not possible therefore to observe their response to anti-anemia therapy. However, it will be observed (Figure 3) that the blood counts

recalculated on the basis of normal blood volumes for individuals of their height (7) suggested that these patients were not actually anemic.

Intraheptol was ineffective and folic acid produced only an insignificant reticulocytosis in A. A. and R. G. (Figures 4 and 5). The hemoglobin and red blood cell values recalculated on the basis of normal blood volumes are again found to be higher than routine blood counts indicated.

Two patients (O. M. and M. F.) had a microcytic hypochromic type of anemia (Figures 6 and 7). Parenteral liver extract which had been given for the patient's liver disease resulted in no alteration in the blood picture of O. M. However, a reticulocyte response followed by

a rise in hemoglobin (determination made at another hospital following patient's transfer) indicates a favorable response to iron in this case. M. F. likewise showed an improvement in her blood count. She received liver extract and ferrous sulfate simultaneously. It was felt that iron alone would probably have been equally effective.

DISCUSSION

In a study of 132 patients with hepatic disorder Wintrobe (9) concluded that, except when hemorrhage or a complicating infection was associated with it, anemia occurring in liver disease was

FIG. 2. FOLIC ACID THERAPY IN A CASE OF CIRRHOSIS WITH MINIMAL HEMATOLOGICAL RESPONSE

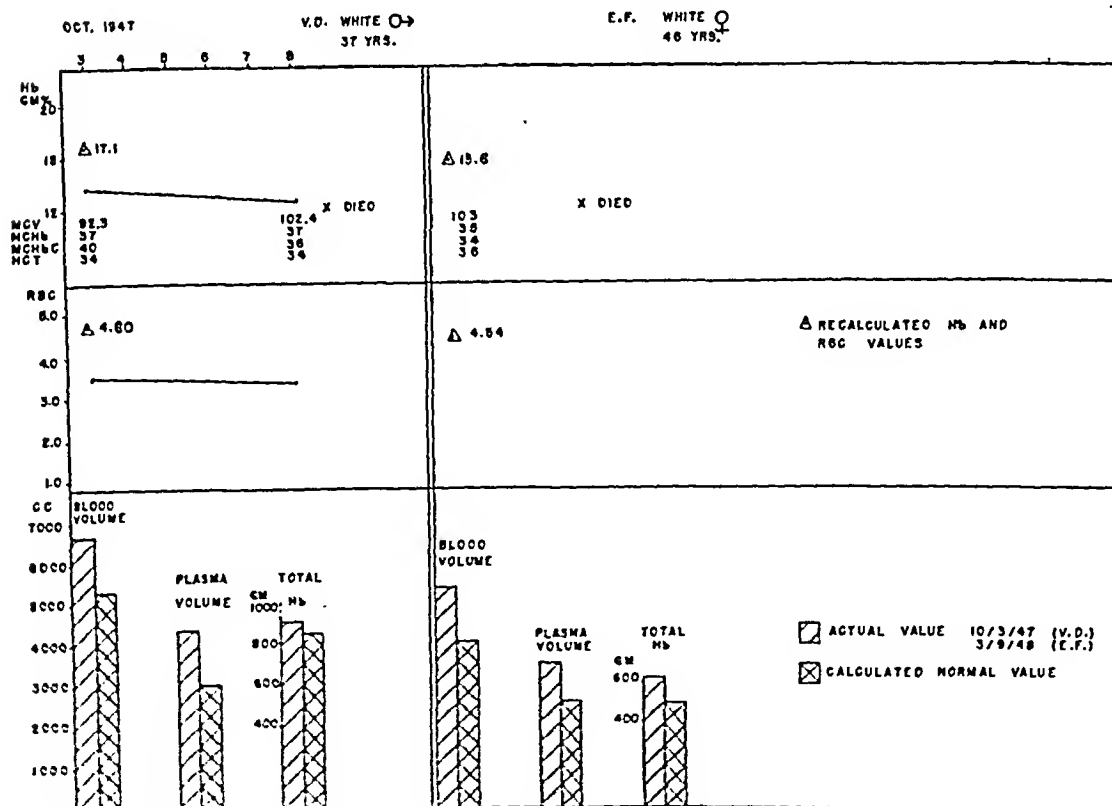

FIG. 3. ACTUAL BLOOD AND PLASMA VOLUMES COMPARED WITH THE CALCULATED EXPECTED NORMAL VALUES IN TWO PATIENTS WHO DIED

Hemoglobin and red blood cell counts recalculated on basis of expected normal blood volumes are shown to be much higher than routine blood counts would indicate.

normocytic or macrocytic. Furthermore when macrocytic anemia was present it was morphologically similar to that seen in pernicious anemia and like the latter manifested spontaneous remissions and was influenced by intramuscular liver therapy. Goldhamer (10) reported a case of cirrhosis of the liver in which free HCl was present in the gastric contents and in which the blood picture simulated that seen in pernicious anemia. There was a response to parenteral liver extract but the figures given suggest that it was very slight. Goldhamer concluded that interference with storage of anti-anemic principle was a factor in the production of macrocytic anemia in cirrhosis. Win-

trobe and Shumacker (11) obtained a clear-cut response to liver therapy in only one out of four patients. Schiff, Rich and Simon (12) prepared extracts from the livers obtained at post mortem from five patients with chronic liver disease, including two with cirrhosis. The extracts were administered to a suitably controlled group of patients with pernicious anemia in relapse. A characteristic reticulocytosis resulted followed by an increase in hemoglobin and red blood cells and marked clinical improvement. This response was attributed to the presence of anti-anemic principle in the liver extract administered.

Hypochromic macrocytic anemia is an infre-

FIG. 4. HEMATOLOGICAL AND BLOOD VOLUME STUDIES IN PATIENT WHO RECEIVED LARGE DOSES OF INTRAHEPTOL AND FOLIC ACID

Hemoglobin and red blood cell values recalculated on basis of expected normal blood volume are seen to be higher than those found on routine counts. Hematological response to therapy poor.

FIG. 5. PROLONGED THERAPY WITH INTRAHEPTOL SUPPLEMENTED BY FOLIC ACID WITH NO APPRECIABLE ALTERATION IN HEMATOLOGICAL PICTURE

Recalculated hemoglobin and red blood cell values 11 grams per cent and 3.02 millions respectively.

quent finding. Davis and Brown (13) describe two cases having mean corpuscular volumes of 100 and 101 cubic microns and mean corpuscular hemoglobin concentrations of 23 and 26 per cent respectively. We had previously noticed the occurrence of this type of anemia in some patients with cirrhosis. In this series of cases three patients (T. M., A. A., R. G.) exhibited a persistently macrocytic hypochromic anemia while in one patient (M. F.) a microcytic hypochromic anemia changed to a macrocytic hypochromic anemia during therapy. The latter finding is probably due to a double deficiency involving depleted iron stores as well as a lack of, or inability to utilize, the erythrocyte maturation factor.

Hypervolemia has been reported as occurring in cirrhosis of the liver (14) as well as in acute liver disease (15). Labby (15) has suggested that failure of the acutely inflamed liver to store blood efficiently may partially explain the concomitant rise in circulating red cell mass found in the latter condition.

Intraheptol is considered to have three units of anti-anemic principle per cc.¹ and would therefore be expected to have an action similar to that of purified liver extract. An extensive literature has recently appeared on the use of folic acid as an effective agent in the treatment of macrocytic anemia of various types (16-24). While the he-

¹ Personal communication from Dr. Elaine P. Ralli.

matological response obtained in pernicious anemia may not be as marked as when parenteral liver extract is used, the results with folic acid are impressive. In sprue and other nutritional macrocytic anemias folic acid therapy compares favorably with liver therapy.

Neither intraheptol nor folic acid altered the hematological status of our patients. The small reticulocyte rise following folic acid administration is considered to be not significant.

When, however, the hematological picture is considered in the light of the marked increase in blood volume it becomes apparent that the majority of these patients actually had either no deficiency in total red cell mass and hemoglobin or only a mild one.

Bleeding phenomena as hematemesis, melena, gingival oozing, and ecchymosis were present or reported in the histories of three male patients. Two of these patients (T. M., R. G.) as well as one (A. A.), whose past history was extremely unreliable, showed a mild hypochromia of the red blood cells with a macrocytosis. Two of the women had a hypochromic microcytic anemia. This is not surprising since mild hypochromic anemia secondary to chronic menstrual blood loss is a common finding. The picture is a little complicated in that both of these patients received liver extract as well as ferrous sulfate. It is interesting to note that the blood picture in M. F. assumed a macrocytic character after her hematological response to therapy. In view of the findings in the

FIG. 6. HYPOCHROMIC MICROCYTIC TYPE OF BLOOD PICTURE SHOWING RESPONSE TO FERROUS SULFATE THERAPY

Blood and plasma volume determinations done on two occasions are markedly above calculated normal values.

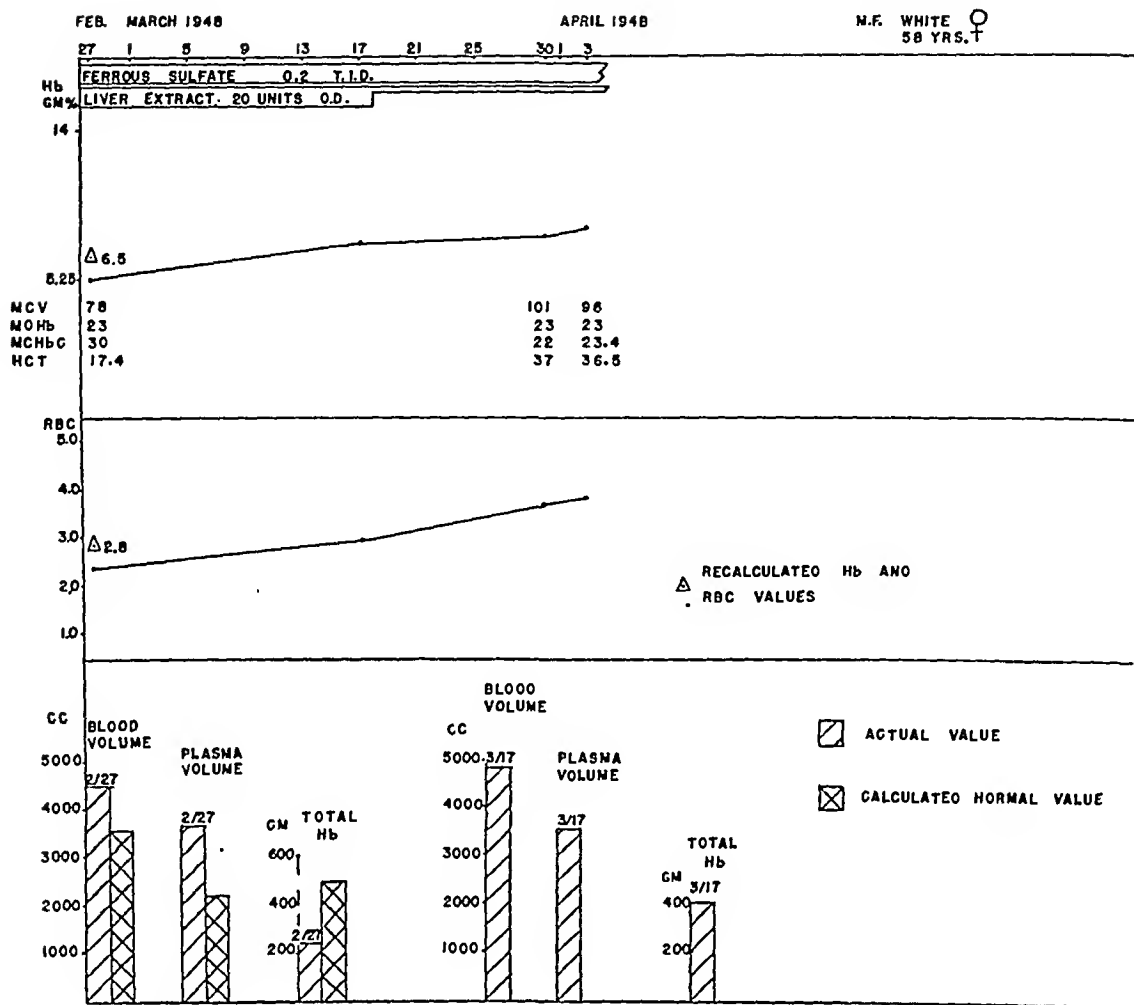

FIG. 7. HEMATOLOGICAL RESPONSE TO LIVER AND IRON THERAPY WITH CHANGE FROM MICROCYTIC TO MACROCYTIC TYPE OF BLOOD PICTURE

other cases reported it is felt that ferrous sulfate alone would have been as effective in these women as when combined with liver extract.

SUMMARY AND CONCLUSIONS

1. The marked increase in total blood volume with a relatively greater increase in plasma than in circulating red cell mass occurring in cirrhosis, when only routine hematological studies are made, suggests a more severe degree of anemia than exists.

2. The presence of an almost normal circulating red cell mass may partially explain the poor response to anti-anemic agents in macrocytic anemia associated with cirrhosis.

3. Hypochromic microcytic anemia occurring in chronic liver disease apparently responds to ferrous sulfate therapy in some cases.

THE EFFECT OF HYALURONIDASE ON THE ABSORPTION OF PARENTERALLY ADMINISTERED RADIOACTIVE PLASMA PROTEINS IN THE DOG¹

By HENRY H. BANKS, ARNOLD M. SELIGMAN, AND JACOB FINE

(From the Kirshtein Laboratory for Surgical Research, Beth Israel Hospital, Boston, and the Department of Surgery, Harvard Medical School)

(Received for publication October 30, 1948)

There are numerous circumstances in which it would be desirable to administer substances subcutaneously, intramuscularly or intraperitoneally that cannot or should not be given intravenously. Since the need for parenterally administered protein and fat is one of the most urgent problems in clinical medicine, we felt it worthwhile to explore the possibility of facilitating their absorption from the tissues by the use of hyaluronidase,² a non-antigenic "spreading factor" first isolated from the testicle (1-3). Sannella (4) observed that this enzyme hastened the absorption of saline solution from the subcutaneous tissues of the rabbit. Hechter (5) found this to be true also in man, not only for saline solution but for plasma as well. Studies were therefore undertaken for a more precise determination of the facts for plasma by the use of plasma tagged with radioactive iodine. Similar observations with respect to fat will be reported (6).

METHOD

Preparation of radioactive iodo-plasma protein

Plasma was iodinated as previously described (7) with the following new modifications. About 2 millicuries of I¹³¹ (as NaI) (half life, eight days)³ were added to 5 mgm. of carrier iodine (as a KI solution) and diluted to 15 cc. with distilled water. One cc. of this solution was diluted 100,000 times with distilled water as standard.

The remaining 14 cc. was mixed with 25 cc. of carbon tetrachloride and to this mixture was added 20 mgm. of potassium iodate and 0.1 cc. of concentrated hydrochloric acid. Free iodine was extracted by the carbon tetra-

chloride, which was separated and added to 500 cc. of plasma (obtained from fresh heparinized dog's blood) containing 20 cc. of 25% sodium carbonate. The violet color of the carbon tetrachloride solution was rapidly discharged on shaking the mixture, which was then allowed to stand for 20 minutes, after which the carbon tetrachloride was separated. The iodinated plasma proteins were then dialyzed in a cellophane bag against cold running tap water for 72 hours to remove unbound ionic iodine. The plasma, now cloudy, was cleared by adding a few grams of sodium chloride and 5-10 cc. of 25% sodium carbonate solution. The volume was measured and 1 cc. was diluted up to 100 cc. and the radioactivity of 1 cc. of this dilution was determined to calculate the per cent of radioactivity incorporated. The pH of the solution was adjusted to 7.4 (glass electrode), with dilute hydrochloric acid. The plasma was then sterilized by Seitz filtration and stored in lead-shielded sterile bottles at 4° C.

Ten to 14% of the radioactive iodine utilized was incorporated in the plasma proteins. The greater the iodine content of iodinated protein, the greater the rate of disappearance from the circulating blood after injection. The iodo-proteins we produced contained about 0.02-0.03% iodine. This amount is well below the upper limit of iodine content required to avoid exceeding the lowest possible degree of denaturation in a protein molecule so tagged. "If one atom of iodine had been incorporated per average protein molecule, the plasma proteins would have contained about 0.2% of iodine, which is the theoretical upper limit of iodine content for obtaining the slowest possible rate of disappearance of a halogenated protein from the circulating plasma" (7), following intravenous injection of iodinated plasma proteins.

Data concerning the stability of the iodine linkage in iodinated plasma protein have been presented previously (7). Examination of a blood specimen, taken 23 days after a dog had been given an injection of radioactive plasma protein subcutaneously, revealed the total absence of radioactivity in the protein free filtrate of the plasma, although considerable radioactivity was present in the plasma. Apparently the radioactive iodine was still bound to the protein.

Animal experiments

Mongrel dogs were given morphine sulfate (2 mgm. per kgm.). Normal oxalated plasma was obtained for preparation of a standard, and the dog then received a

¹ Aided by a grant from the Patrons of Research of the Beth Israel Hospital, Boston.

² The hyaluronidase used in these experiments was obtained as "Hyronase" through the courtesy of Schering Corporation, Bloomfield, New Jersey. The preparation used contained approximately 50 turbidity reducing units per mgm.

³ Obtained from Monsanto Chemical Corporation, Oak Ridge, Tennessee.

* About six weeks elapsed between each injection in order to allow the radioactivity in the blood plasma to disappear completely.

subcutaneous injection in the thigh of 10 cc. per kgm. of sterile radioactive plasma proteins. Blood specimens for radioactivity determinations were then taken from the opposite leg at or about the following intervals, in hours: 1, 3, 5, 8, 12, 24, 36, 48, 72, 96, 120, 144 and 168. When the radioactivity of the plasma reached zero, usually at the end of about six weeks, the same animal received a subcutaneous injection in the opposite thigh of 12 TRU⁴ of hyaluronidase in 10 cc. of sterile normal saline followed at once by 10 cc. per kgm. of sterile radioactive plasma proteins.⁵ The injection was given slowly and gently into the subcutaneous space and without producing undue tissue pressure. The time required for the mass of subcutaneous fluid to disappear was observed. The thigh injected was immobilized for 12 hours to prevent the introduction of error due to motion or pressure.

When the radioactivity of the plasma again reached zero, the dog was given 10 cc. per kgm. of sterile radioactive plasma protein intravenously in order to observe its rate of disappearance from the blood. For this purpose, samples were drawn at about the same intervals mentioned previously.

⁴ TRU—Turbidity reducing units.

⁵ It has been observed that the spreading response induced by hyaluronidase is influenced by the enzyme concentration and the volume of injection (8). To employ the best conditions for the action of hyaluronidase, 240 µg. of the enzyme or at least 10 times that ordinarily recommended and a volume of plasma protein larger than the potential volume of the injection site were used. The thigh was used because of the tightness of the tissues in this area.

Because of the variation in the rate of absorption from dog to dog, it was found necessary to use the same animal for all three parts of the experiment. Five such experiments were completed. Similar experiments were carried out on two dogs in which radioactive plasma was injected intraperitoneally instead of subcutaneously.

Measurement of radioactivity

Plasma (1 cc.) was evaporated in an aluminum cup to dryness at 37° C. for 24 hours. The radioactivity of this preparation was compared with a standard which was similarly prepared after adding 0.2 cc. of the original radioactive plasma used for the injection to 1 cc. of non-radioactive plasma prepared from the blood sample taken from each dog just before it received the radioactive plasma.

All specimens were measured for radioactivity with a Tracerlab Autoscaler and bell type G.M. tube with mica window (4 mgm. per sq. cm.), shielded with 1.5 inches of lead. All readings were at least five times background. The percentage of injected radioactivity circulating in the blood plasma was calculated by the following formula:

% circulating radioactivity

$$= \frac{\text{activity in counts per minute of 1 cc. of plasma} \times \text{estimated plasma volume} \times 100}{\text{activity of 0.2 cc. of injected radioactive plasma} \times 5 \times \text{dilution factor}^6 \times \text{number cc. injected}}$$

⁶ In some cases it was necessary to dilute the radioactive plasma 100 times before preparing the standard with 0.2 cc. and 1 cc. of non-radioactive plasma.

FIG. 1. RATE OF ABSORPTION INTO BLOOD OF INJECTED RADIOACTIVE IODO-PLASMA PROTEIN

The hematocrits of several dogs averaged 50%. Assuming the blood volume to be 10% of the body weight, the plasma volume was estimated to be 5% of the body weight. Table I shows the results of these calculations for all experiments. The results of the three series of observations in each experiment were plotted for comparison. In Figure 1 the disappearance of radioactivity from the plasma after administration by three techniques is shown for one dog.

It will be noted that the disappearance rate of radioactivity after an intravenous injection of radioactive iodo plasma proteins is faster than that observed by Fine and Seligman (7). This may be due to the fact that more denaturation of the plasma protein may have been produced with sodium carbonate treatment or by the use of HCl for the adjustment of the pH to 7.4.

In order to compare the quantity of radioactive plasma, with and without hyaluronidase, absorbed into the circu-

* The data are given in per cent and were calculated by a planimeter determination of the area under the blood plasma concentration curve for each experiment at various time intervals from zero. The area under the curve after the intravenous injection is taken as 100% for each interval. See Figure 1 for an example of these blood curves in experiment 4.

† Several weeks were required between each injection in order to allow the radioactivity in the blood plasma to disappear.

lation from the tissues at any given time with the amount remaining in the circulation after an equal interval following an intravenous injection, the area under each curve for a given time interval was measured by means of a planimeter. The area under the curve of the intravenous injection was taken as 100% for each time interval. Table II presents these data, comparing the results among the various dogs.

RESULTS

The results tabulated in Table I show that in three dogs out of five the effect of hyaluronidase is noted within one hour after the subcutaneous administration of radioactive iodo-plasma proteins. As the concentration levels indicate, the presence of hyaluronidase increases the absorption of the radioactive plasma proteins into the circulation two to three times that without it. Within five hours, similar results are observed in four out of five dogs; within eight hours, similar results are observed in all dogs. Within 36 hours, the rising concentration of circulating radioactivity tapers off. Within 96 hours, the concentration of circulating radioactivity is the same as without the enzyme in two dogs, but is one and one-half to two times that without the enzyme in three dogs.

Similar conclusions are derived from a comparison of the quantity of circulating radioactivity at various time intervals from zero after the subcutaneous injection of radioactive iodo plasma proteins (with and without hyaluronidase) with the quantity of circulating radioactivity at similar intervals after the intravenous injection of the same amount in the same dog (Table II). In 24 hours after subcutaneous injections, the amount of circulating radioactive plasma proteins were twice as much in three, and one and one-half times as much in two dogs receiving hyaluronidase, as compared to five dogs not receiving the enzyme. This difference persists to a somewhat lesser degree for the duration of the experiment. By comparing these quantities of circulating radioactive plasma with that following an intravenous administration, it appears that within 120 hours, 90% of an injection of radioactive plasma protein was absorbed in four out of five dogs receiving hyaluronidase, whereas less than 70 % was absorbed after the same period when no hyaluronidase was given.

It was observed by Hechter (5) that the addition of hyaluronidase to a saline clysis allowed four

and one-half times as much fluid to run into the tissues in a given interval, while a given volume of fluid was taken up 12 times faster. These data do not necessarily reflect accurately the rate of absorption into the circulation. Figure 1 and Tables I and II show that hyaluronidase increases the rate of absorption into the blood of radioactive iodo plasma proteins given subcutaneously, one and one-half to three times. The increased rate for saline presumably would be greater. The increased rate of absorption is an indirect effect of the spreading action of hyaluronidase.

Without hyaluronidase the tension in the dog's thigh at the site of the injected plasma remains high for at least one hour and then diminishes slowly. The fluid mass disappears within four to seven hours. When hyaluronidase is added to the plasma proteins, the fluid mass from the beginning is not tense, but soft, and completely disappears within one hour. As expected, the discomfort due to tension is therefore avoided.

It may be conjectured that pressure may facilitate the spreading out and disappearance of a fluid mass just as hyaluronidase does. The data of such an experiment (Table III) were obtained when a dog turned itself so as to lie on the injected site. It will be observed that the peak of circulating radioactivity was not reached until 48 hours after that observed in a hyaluronidase experiment in the

† Percentage of total radioactivity injected.

same dog. The peak level in both experiments was about equal but considerably greater than in the control. Pressure, therefore, by virtue of dissemination, increases the rate of absorption. The rate of increase presumably is related to the degree of pressure applied, but pressure seems to be less efficient than hyaluronidase as a spreading agent.

In three preliminary experiments, which are not included in this series, abscesses developed at the site of injection, probably because unsterile radioactive plasma proteins were used at that time. The repeated injection of hyaluronidase into these areas did not seem to increase the extent of infection.

Inasmuch as hyaluronidase is considered to be a protein-like substance, it might be expected to be antigenic. The repeated injection of 240 μ g. in all dogs used in these experiments resulted in no evidence of anaphylaxis.

In two experiments, hyaluronidase did not increase the rate of absorption of radioactive iodo plasma proteins administered intraperitoneally (Table IV). This is consistent with the assumption that hyaluronidase acts by depolymerizing the intercellular cement substance.

CONCLUSIONS

1. Hyaluronidase increases the rate of absorption of plasma proteins injected subcutaneously, one and one-half to three times.
2. It is not antigenic in the doses used herein.
3. It acts more efficiently than pressure.
4. It does not increase the rate of absorption of plasma proteins administered intraperitoneally.

Acknowledgment for technical assistance is due Mr. Thomas W. Barnett.

THE ACCELERATION OF LINEAR FLOW IN THE DEEP VEINS OF THE LOWER EXTREMITY OF MAN BY LOCAL COMPRESSION¹

By JOSEPH R. STANTON, EDWARD D. FREIS, AND ROBERT W. WILKINS

(From the Robert Rawson Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine, Boston, Mass.)

(Received for publication November 26, 1948)

INTRODUCTION

With the increasing age and life expectancy of the population (1) and the higher incidence of thromboembolic disease in older age groups (2-4) the problems of phlebothrombosis are becoming increasingly urgent. Particularly needed is more information concerning the etiology and pathologic physiology of venous thrombosis, so that adequate measures may be taken to prevent its consequences. The present communication presents the results of experiments upon one of the factors recognized as important in the formation of intravenous clots, namely, the velocity of venous flow.

In 1856, Virchow postulated that alterations of the blood current, of the blood chemistry and of the blood vessel wall, are factors important in the etiology of venous thrombosis (5). Since then numerous papers have been devoted to alterations of the vessel wall and of the blood chemistry and morphology but only scant and sporadic attention has been paid to changes in the venous current. It has been shown by careful pathological and roentgenographic studies that the deep venous system of the calf is the most important site of development of phlebothrombosis leading to pulmonary embolism (6-10). It has also been suspected that slowing of the venous current contributes to this situation (11-14). However, as yet, no one has related a slowing of flow to anatomic abnormalities in the deep veins of the leg nor has the effect of compression on the velocity of flow been previously reported. In this study particular attention was paid to the general form of the deep veins of the calf as well as to the velocity of flow and the effects of local compression.

MATERIAL AND METHODS

The subjects were a group of 12 male and eight female patients from the ward and private services of the Massa-

chusetts Memorial Hospitals. Their ages ranged from 17 to 70 years. All subjects were studied after resting for 45 minutes in a quiet room the temperature of which was maintained relatively constant ($\pm 2^\circ$ C.).

With the patient supine upon the X-ray table the entire lower extremity from the instep to the upper third of the thigh was encased in a series of loosely fitting blood pressure cuffs or in an inflatable legging (of a G-suit). The heel was elevated so that the calf was free of the table and the leg was immobilized by properly applied sandbags at the foot.

A 20 gauge, 1½-inch needle was inserted through procainized skin into a distal vein on the dorsum of the foot in such a fashion that the tip of the needle was well within the pressurized area when the G-suit or cuffs were inflated. To the needle was attached a three-way stopcock and tubing leading to an infusion of normal saline solution which was allowed to flow at a constant slow rate for the purpose of keeping the needle patent between injections. All injections of test substances were made directly into the vein through the side arm of the three-way stopcock. After control observations were completed the limb was pressurized by inflating the garment or blood pressure cuffs at pressures of 20 or 35 mm. Hg, whereupon the test procedure was repeated.

In two patients an additional 18 gauge, two-inch needle was placed in the femoral vein just proximal to the upper margin of the inflatable garment. To this a five-inch segment of an 18 F nylon catheter was attached so that blood samples could be collected in oxalated tubes every four seconds. Three cc. of 0.5% Evans Blue Dye (T-1824) were injected into the foot vein. Blood samples were then collected from the femoral vein for periods of 50 to 100 seconds. This procedure was carried out before and during the application of pressure as described above. The blood samples were centrifuged at 3,000 R.P.M. for 30 minutes and the supernatant plasma after appropriate dilution was analyzed for dye concentration using the Coleman photoelectric colorimeter. Thus, the appearance, maximum concentration, and disappearance of the dye in the femoral vein were accurately timed.

The test substances used in carrying out these experiments were solutions of 35% Diodrast, 20% Decholin sodium,² and 0.5% Evans Blue Dye (T-1824).³ Diodrast was not given to patients with a history of allergy or previous diodrast reactions, and decholin was not administered in the presence or history of jaundice or liver

disease. All injections were made by the same person who carefully timed the rate of injection. When discrepancies in the rate of injection occurred, the test was discarded or repeated. Stopwatches were calibrated to one-tenth of a second.

RESULTS

A. Appearance time

In the early phases of this investigation two independent observers noted through a fluoroscopic screen the time required for a 4 cc. dose of diodrast to pass from the needle to a lead marker applied to the upper third of the calf. The time from the start of injection until the dye reached the marker was noted and termed the appearance time. When the control observations were completed the limb was pressurized at 20 mm. Hg and then the procedure repeated.

Fifteen control observations were made in eight cases before the application of pressure and were compared with 11 observations made during pressurization of the limb at 20 mm. Hg. The control mean appearance time was 21.78 seconds as contrasted with a mean appearance time of 11.38 seconds during pressurization (Table I).

B. Linear velocity of flow

Because the method reported above was open to certain criticisms and also because in some instances the deep veins of the calf were poorly visualized during fluoroscopy, it seemed desirable to confirm these results, if possible by more accurate methods. To this end lead markers were fixed at specific intervals on calf and thigh and the distance

between the markers carefully measured, so that the linear velocity in centimeters per second could be determined.

After observing fluoroscopically the appearance time of the diodrast in the calf and allowing 15 minutes for all the injected dye to be cleared from the veins, the dye was again administered and serial roentgenograms of the calf and thigh taken at exactly timed intervals during the period that diodrast would be expected to be in the field under study. Another pause was allowed for clearing, and the limb was then pressurized at 20 mm. Hg. Five minutes later the test was repeated and roentgenograms taken at exactly the same intervals as before. In three patients simultaneous control observations were made on the opposite extremity subjected to the same procedures as the experimental limb except that it was never pressurized.

As might be expected, technical difficulties including the exacting team work required, proper positioning of the limb, the absolute necessity for immobility of the subjects, and limitations imposed by the amount of X-ray to which any one patient might be safely exposed, prevented this technique from yielding results that could be accurately interpreted in every experiment. As a matter of fact, in several experiments a marked increase in velocity during pressurization resulted in the dye having already left the field by the time the thigh film was taken during pressurization. However, in no experiment could the results be interpreted as indicating that pressurization had decreased the velocity of venous flow. On the contrary, in practically every experiment, particularly when the

major portion of the diodrast entered the deep venous system of the leg, the velocity of flow was unquestionably increased, in some instances to a striking degree.

Figure 1 illustrates unretouched photographs of serial roentgenograms of the dye in the deep veins of the calf and thigh of a 48-year-old female before and during the application of 20 mm. Hg pressure. The calf films were taken 10 seconds and the thigh films 30 seconds after the injection. It is obvious that the injected diodrast moved at a markedly increased velocity when the limb was pressurized.

The results of such studies in five cases suitable for analysis are recorded in Table II. In each instance the application of pressure resulted in a definite increase in the linear velocity as determined by this technique. The mean increase in four cases was 45.4 per cent and the range 22 to 75 per cent while in the fifth case linear velocity was increased by 131 and 170 per cent in two tests.

Simultaneous observations in the control limb showed insignificant changes as compared with the

pressurized limb, while repetition of the test in the experimental limb in two of five cases after the release of pressure revealed the velocity of flow to have returned to pre-pressurization values.

C. Circulation times

1. Foot-to-tongue

Additional corroborative evidence of the acceleration of venous flow during the application of

TABLE III

Effect of pressurization on the foot-to-tongue circulation time as measured by decholin sodium

Patient	Age	Circulation time (sec.)		Per cent decrease in circulation time during pressurization
		Control	During pressurization	
T. A.	24	37	18.2	51

R. H.	72	27.5	17.5	36
S. M.	69	48.5	35.7	26
H. E.	67	87	62	29
H. U.	33	49	41	16

pressure was obtained by foot-to-tongue (Decholin) circulation times in six cases. The circulation times in all instances during pressurization were decreased. The percentage decrease ranged from 16 to 51 with a mean of 29 per cent (Table III).

2. The foot-to-femoral vein circulation time as measured by Evans Blue Dye (T-1824).

The limb venous circulation time was estimated in two cases before and during the application of pressure, by measuring the concentration of injected dye in consecutive four-second samples from the femoral vein. In both cases the appearance time of the dye was markedly decreased during the application of pressure.

Figure 2 illustrates the results of this procedure in a 44-year-old male. It is noteworthy that the dye before pressurization was not present in the femoral vein until 20 seconds after injection at the

FIG. 2

Illustrates the effect of pressurization of the extremity on the appearance time and concentration curve of Evans Blue Dye (T-1824) in plasma samples obtained by continuous sampling from the femoral vein.

foot whereas during pressurization it was present in 12 seconds. In addition, the shape of the concentration curves indicated that the veins were cleared of the injected dye in less time during the application of pressure. These findings indicate the velocity of venous flow was increased as measured by this technique.

Additional observations

In the course of this investigation the following collateral observations were made upon the size and shape of the leg veins and are reported because of their probable influence upon velocity of venous flow.

(a) In younger individuals the deep veins of the calf were noted usually to be narrow and straight as delineated by the contrast medium, which moved along rapidly in them. In older individuals, particularly those over 40, the deep veins not infrequently exhibited saccular dilations in which the diodrast tended to puddle, often remaining as long as 15 minutes.

(b) Veins well filled with diodrast as viewed in serial roentgenograms frequently exhibited a measurable decrease in diameter during the period of local compression along with the concomitant increase in linear velocity of flow.

(c) The application of pressure usually did not alter the distribution of the diodrast between the superficial and deep venous systems of the extremity, but rather accelerated the flow in both.

(d) Increasing the pressure from 20 to 35 mm. Hg did not cause a perceptible further increase in the velocity of venous flow.

(e) In six patients the velocity of venous flow as judged from the foot-to-tongue and foot-to-pharynx circulation times was similarly accelerated whether the source of local compression was an inflatable legging, an elastic stocking or a carefully applied elastic bandage.

(f) When diodrast was well visualized in the veins of the leg during pressurization it was usually present for a shorter total time than during the control period. This finding and the concentration curves of Evans Blue in femoral vein blood both suggest that the "venous emptying time" (13) was decreased by the application of pressure.

DISCUSSION

It is recognized that large changes in the skin temperature of the digits may alter the circulation time, as demonstrated by Smith, Allen and Craig (11) and Stead and Kunkel (15). It is also obvious that a certain velocity is imparted to the test substances in the process of injection. In the present study diligent efforts were therefore made to control both factors. Furthermore, collateral studies of foot-to-tongue circulation times and simultaneous skin temperatures of the toes failed to reveal more than slight changes in the temperatures when the velocity of venous flow was increased during mild pressurization (16). The magnitude and uniformity of the velocity changes *observed strongly suggest that the linear velocity of venous flow in the leg veins is increased by the local application of pressure.*

Ochsner has recommended compression of the limbs by elastic bandages as a prophylactic measure against phlebothrombosis and pulmonary embolism in surgical patients, on the supposition that compression of the superficial veins would drive more blood through the deep vessels and thus accelerate flow in these channels (17). In the present study the application of pressures of 20 to 35 mm. Hg seldom altered the distribution of the injected diodrast in the deep and superficial veins but did accelerate the flow in both.

It has been reported previously from this laboratory that the local application of pressures of as little as 30 mm. Hg decreases the *volume* of blood flow into the limbs (18). The present experiments demonstrate that in spite of the decrease in volume of arterial blood flow into the limbs there is simultaneously during mild pressurization an increase in linear velocity of venous flow from the limbs. The observation that the veins appear smaller during compression suggests that the observed acceleratory effect is due primarily to a disproportionately greater decrease in cross-sectional area of the venous bed than the decrease in the volume of blood flow into the limbs during such compression. It is significant that marked increases in the linear velocity of venous flow could be produced by the local application of pressures of as little as 20 mm. Hg pressure. Since this pressure (in contrast to higher pressures) causes only slight decrease in inflow (18), it is

probably near the optimum pressure for the maximum acceleratory effect. The possible therapeutic applications of this principle are now under study in this clinic.

SUMMARY AND CONCLUSIONS

1. The application of local pressure of 20 to 35 mm. Hg to the lower extremity of human subjects increased the velocity of venous flow—as measured by fluoroscopy, serial roentgenograms, foot-to-tongue circulation times, and limb venous circulation times.

2. Pressures of 20 mm. Hg applied to the lower extremities of man significantly increased the linear velocity of flow in the deep veins, but did *not alter significantly the distribution of injected diodrast between the superficial and deep venous channels.*

3. It is suggested that the mechanism of the increase in linear velocity of venous flow during local compression is the concomitant decrease in the total cross-sectional area of the venous beds.

The authors are genuinely indebted to Doctors George Levene and Harry Lerner and to Miss Anne Lally and the X-ray technicians of the Department of Radiology of the Massachusetts Memorial Hospitals for cooperation and aid in carrying out the radiographic techniques employed in this study.

THE EFFECT OF EXERCISE AND BODY POSITION ON THE VENOUS PRESSURE AT THE ANKLE IN PATIENTS HAVING VENOUS VALVULAR DEFECTS¹

BY ALBERT A. POLLACK,² BOWEN E. TAYLOR,² THOMAS T. MYERS,
AND EARL H. WOOD

(From the Divisions of Medicine, Postoperative Care and Physiology, Mayo Foundation
and Mayo Clinic, Rochester, Minn.)

(Received for publication December 4, 1948)

The purpose of this investigation was to determine directly and record continuously the effects of body position and of walking on the venous pressure at the ankle in patients having incompetent veins of the lower extremity. Smirk (1), in 1936, reported the first direct measurement of venous pressure at the ankle during walking. His measurements were made on one normal subject. Beecher, Field and Krogh (2), in the same year, reported on the indirect measurement of the venous pressure in the human leg during walking. Others (3-7) have reported the effects of exercise and position on the venous pressure in the leg measured both by direct and by indirect methods. Recently Pollack and Wood (8, 9), and Henry (10) have given preliminary reports of direct studies of venous pressure in the human leg during walking.

In the present study the venous pressure was recorded photographically by means of an electrical strain-gauge manometer (11).³ The manometer was attached to the subject's lower extremity by means of a specially constructed aluminum support that was taped to the lateral surface of the leg. Care was taken that no tape was placed over the vein to be used for measurement of the pressures. The manometer was coupled to this aluminum support with two double-ended universal clamps (Figure 1).

Polythene tubing 15 cm. long with an internal diameter of approximately 0.5 mm. was used as a venous catheter.⁴ A venipuncture was performed with a number 17 needle in the great saphenous vein as it passes anterior to the medial malleolus. The catheter was passed through the

needle into the vein for a distance of about 10 cm.; then the needle was withdrawn, leaving the catheter in place. The manometer system was flushed frequently with heparinized saline solution.

Respiration was recorded by means of a thermocouple mounted in a plastic nose piece. The heart rate and the electrocardiogram were measured through a Sturm and Wood cardiotaehometer (12).

The venous pressure was recorded continuously in the supine, sitting and resting standing positions. After these maneuvers the patient walked on a horizontal power-driven treadmill at 1.7 m.p.h. for periods ranging from 15 to 60 seconds.

The vertical distance between the tip of the catheter and the third thoracic interspace was measured in the sitting and standing positions. The hydrostatic pressure exerted by a column of blood extending over this distance was calculated, 1.06 and 13.55 being used as the specific gravity of blood and mercury respectively. The zero base lines in the sitting and standing positions were determined by recording the pressure when the surface of a column of fluid in a tube (1 cm. internal diameter) connected to the catheter was held on the surface of the leg level with the position which had been occupied by the catheter tip in the lying, sitting and standing positions. This procedure was necessary in order to avoid errors due to capillarity of the catheter.

RESULTS

In the supine position the average venous pressure in seven patients with primary varicose veins⁵ was 7.2 mm. of mercury with a range from 5.7 to 8.5 mm. In six patients with incompetent superficial (greater saphenous) veins associated with a history of previous iliofemoral thrombophlebitis⁶ the average venous pressure was 10.7 mm. with a range from 8.3 to 14 mm. of mercury in the supine position. In the sitting position the average venous pressure at the ankle in ten patients with

⁵ This term has been used to indicate uncomplicated varicosities of the greater saphenous system.

⁶ These patients clinically appeared to have chronic venous insufficiency of the deep veins in addition to varicosities of the superficial system.

incompetent veins of the lower extremity was 52 mm. of mercury with a range from 31 to 61 mm. The average venous pressure at the ankle in the resting standing position was 81.9 mm. of mercury with a range from 63 to 97 mm. (Table I).

In the sitting position, the average difference between the measured venous pressure and the calculated hydrostatic pressure of a column of blood extending from the third thoracic interspace to the ankle was 0.3 mm. of mercury. In the standing position, this difference was 0.6 mm. (Table I). It is evident that while the patient is at rest in the sitting or standing position the venous pressure at the ankle is sufficient to support a column of blood approximately up to the third thoracic interspace, the level of the middle of the right atrium (13).

In seven patients who had primary varicose veins, walking at 1.7 m.p.h. uniformly produced a decrease in the mean venous pressure at the ankle averaging 37.4 mm. of mercury with a range from 29.5 to 47.4 mm., which was maintained for the

duration of the 30-second to 60-second period of walking (Table II). In six patients who had incompetent greater saphenous veins and a history of previous iliofemoral thrombophlebitis, walking produced an average fall of only 11.1 mm. of mercury in the mean venous pressure at the ankle (Table III). The decrease in venous pressure at the ankle in normal subjects produced by walking 1.7 m.p.h. averaged 64 and ranged from 54 to 71 mm. of mercury.

In the patients who had uncomplicated greater saphenous vein incompetency the average time required for the venous pressure to return to the resting standing level after the walk was completed was 2.8 (1.2 to 5.5) seconds as contrasted to the 31 (8 to 57) seconds required in normal subjects (9) (Figure 2a and b).

In the normal subjects after the initial one or two steps of walking the maximal venous pressures generated during subsequent steps of the walk were considerably less than the control resting standing pressure (Figure 2a) (9). In patients who had

uncomplicated valvular defects of the greater saphenous system, the maximal pressure exerted during the stable period approached and frequently equaled the resting standing pressure (Figure 2b). In the patients who had incompetency of the greater saphenous vein and a previous iliofemoral thrombophlebitis the maximal pressure during each step usually exceeded the hydrostatic pressure throughout the period of walking. In these patients the maximal venous pressure during the steps within the stable pressure period of the walk averaged 29 mm. of mercury greater than the resting standing value (Figure 2c). After walking, the venous pressure at the ankle in normal subjects and patients who had uncomplicated greater saphenous incompetency returned to the resting

umn of blood up to the level of the right atrium (1, 5-10). The decrease of venous pressure at the ankle in normal subjects produced by walking on a horizontal treadmill is due to the pumping action of the muscles and the competency of the venous valves in preventing reflux of blood into the emptied segments of the veins during the period of muscular relaxation (9). In patients who have uncomplicated primary varicose veins, the valves are unable to prevent the return flow of blood during muscular relaxation and the venous pressure returns relatively quickly to the hydrostatic level, thus accounting for the higher mean pressure during the walk and rapid return to the hydrostatic control level after the walk has been completed.

Interpretation of the genesis of the venous pressure tracings obtained from patients who have incompetent great saphenous veins and a history of previous iliofemoral thrombophlebitis is un-

certain. At first it would appear that there was interference with the outflow of venous blood from the leg in this condition. The higher resting standing pressure at the end of the walk than at the beginning, the higher mean pressure during the stable period, and the marked rise above hydrostatic levels during each step of the stable walking period as contrasted to those obtained from patients having primary varicose veins point to this explanation. However, the fact that no significant difference was found between the extremes of pressures of the individual steps during walking in patients who had primary varicose veins and in patients who had incompetency of the superficial system and a history of iliofemoral thrombophlebitis does not support this interpretation. Even with a critically damped manometer system the effects of acceleration generated by the motions of walking on the manometer and hydrostatic systems are difficult to control. Therefore, the sig-

nificance of the contours and extremes of the pressure variations recorded during walking is difficult to assess. The use of mean pressures, as determined by planimetry, is much less subject to criticisms of this type.

The fact that in four patients suffering from cardiac disease, who had elevated resting standing venous pressure at the ankle due to cardiac causes, the venous pressure at the ankle decreased during walking to the same range as in normal subjects indicates that the venous valves and the action of voluntary muscles have more to do with the regulation of venous pressure in the leg than does central venous pressure (14).

It is not inconceivable that determinations of venous pressure at the ankle during exercise may be used as a diagnostic aid, and as a means of assaying the efficacy of surgical treatment of abnormalities in the venous systems of the leg.

SUMMARY AND CONCLUSIONS

Venous pressure in the greater saphenous vein at the ankle was studied in 13 patients with varicose veins while resting in the recumbent, seated and standing positions and while walking on a treadmill.

Confirmatory data were obtained indicating that the venous pressure at the ankle in the resting, sitting or standing positions in normal subjects and patients with incompetency of the saphenous veins is sufficient to support a column of blood to approximately the level of the third thoracic interspace.

Walking on a level treadmill at 1.7 miles per hour produced an average decrease in mean venous pressure at the ankle of 37 (30 to 47) mm. of mercury in seven patients with primary varicose veins and 11 (5 to 13) mm. of mercury in six patients with varicose veins associated with a history of a previous iliofemoral thrombophlebitis. In normal subjects this value was 64 (54 to 71) mm. of mercury.

In patients who had uncomplicated incompetency of the greater saphenous vein the average time required for the venous pressure to return to the resting standing level after cessation of walking was 2.8 (1.2 to 5.5) seconds. In those patients with a history of previous iliofemoral thrombophlebitis the pressure rose to levels slightly in excess of the control resting value

within one second after completion of the walk as contrasted to the 31 (eight to 57) seconds required for the pressure to return to the control values after walking in normal subjects.

These data are in harmony with the concept that the function of the venous valves in conjunction with the action of voluntary muscles is of primary importance in the regulation of venous pressure at the ankle.

THE INHIBITION OF FROSTBITE WHEELS BY THE IONTOPHORESIS OF ANTIHISTAMINIC AGENTS¹

BY MARTIN B. MACHT,² MORTIMER E. BADER,³ AND JERE MEAD³

WITH THE TECHNICAL ASSISTANCE OF ELIZABETH L. PILLION

(From the U. S. Army, Quartermaster Climatic Research Laboratory, Lawrence, Mass.)

(Received for publication December 17, 1948)

Skin whealing associated with localized frostbite is a well recognized phenomenon and has been described in detail by Lewis and his co-workers (1, 2). Although no positive evidence of histamine liberation in frostbite has been advanced, it has been postulated that histamine or a histamine-like substance is involved in the formation of these lesions (2). Recently, Frommel and Picquet have reported beneficial results from the antihistaminic drug, dimethylaminoethyl-ethylbenzylaniline hydrochloride (Antergan), in the treatment of frostbite in guinea pigs (3).

The inhibition of histamine wheals by the oral or intradermal administration of beta-dimethylaminoethyl benzhydryl ether (Benadryl, Parke-Davis) and N'pyridil-N'benzyl-N'dimethylethylenediamine hydrochloride (Pyribenzamine, Ciba) has been demonstrated conclusively (4-6). A similar inhibition can be achieved locally by the iontophoresis of Pyribenzamine (7).

In an effort to gain additional information regarding the role of histamine in the pathogenesis of local frostbite, we have studied experimentally produced frostbite lesions before and after the iontophoretic administration of Benadryl and Pyribenzamine. The results obtained are presented in this paper.

METHODS

Twelve healthy young males were used as subjects. The ventral surfaces of the forearms and/or thighs were shaved. By means of an ordinary iontophoresis apparatus, various test solutions were introduced into rectangular areas of skin measuring 5 × 5 cm. The positive electrode

was constructed of copper screening covered with flannel. The flannel was saturated with the solution to be tested and was secured firmly to the skin by means of a canvas strap. A current density of 0.5 milliamperes per sq. cm. was applied for four minutes in each case. The solutions introduced by electrophoretic means were (1) 0.9% NaCl, (2) a saturated solution of Pyribenzamine hydrochloride, and (3) a saturated solution of Benadryl hydrochloride. Since each subject acted as his own control, the various solutions were usually applied to the same extremity in rectangular areas one inch apart. In those cases in which sufficient surface area was not available, Pyribenzamine and a saline control were placed on the skin of one extremity, while Benadryl and a saline control were applied in a similar manner to the skin of the opposite extremity. After one hour the erythema which routinely followed the iontophoresis of any of the solutions had usually disappeared. Localized frostbite was then produced by means of a jet of cold air directed at the skin. The air was first dried and was then passed through coils of copper tubing embedded in an insulated cask of dry ice. The rate of flow was measured by means of a standard gasometer placed in the system, and the temperature of the air was determined by means of a thermocouple placed at the end of a 16-inch length of 3/8-inch rubber tubing which served as the outlet. Although the intensity and duration of the stimulus varied somewhat from subject to subject, the same stimulus was always applied to the areas tested on any particular subject during a single experiment. It was found that a jet of air at a temperature of -40° F. applied for ten seconds resulted in satisfactory and reproducible lesions. In a single experiment the same cold stimulus was applied to each of the treated areas and to one untreated area nearby. Observations were made of the time of onset, degree and size of wheal formation.

RESULTS

During, and for a short time following, the iontophoresis of any of the substances used, the subjects reported slight discomfort, usually described as "burning or tingling" at the site of application. This discomfort was equally great whether saline, Benadryl, or Pyribenzamine was used. Similarly, no differences between the saline control and the anti-histaminic agents were noted with regard to local erythema or papule formation.
